Mitochondrial fusion depends on ATP (Schauss *et al.*, 2010). Chan and colleagues recently demonstrated using an *in vitro* fusion assay with isolated mitochondria that mitochondrial MIM fusion, but not MOM fusion, is sensitive to the state of oxidative phosphorylation or cellular metabolic states; the metabolic states regulate MIM fusion through the activation of Yme1L-dependent S2 cleavage of L-Opa1, suggesting a mechanism linking mitochondrial fusion with cellular metabolic states (Mishra *et al.*, 2014).

Langer and colleagues, using cell lines lacking either or both YME1L and OMA1, recently demonstrated that Opa1 processing is dispensable for mitochondrial fusion and further revealed an unexpected stimulatory role of S-Opa1 in mitochondrial fission under conditions in which membrane fusion normally proceeds (Anand *et al.*, 2014). Conceivably, S-Opa1 interacts with the fission machinery at the MOM or is involved

in MIM fission. Interestingly, S-Opa1 with the GTPase mutation partly localizes in the ER-mitochondria contact sites and mitochondrial fission machinery as punctate structures (Anand *et al.*, 2014).

Molecular Insights into Drp1 Actions During Mitochondrial Fission

Drp1, a Key Player

Drp1 is a member of the conserved dynamin GTPase superfamily, which includes a broad range of membrane fission proteins, and mediates mitochondria and peroxisome fission events. Drp1 is a cytosolic protein with an N-terminal GTPase domain thought to provide mechanical force, a dynamin-like middle domain, and a GTPase effector domain (GED) located in the C-terminal region (Figure 4). A dominant-negative middle domain mutation (A395D) in Drp1 was reported in a patient with a lethal disorder exhibiting microcephaly, abnormal brain development, optic atrophy, and hypoplasia (Waterham *et al.*, 2007). Cells derived from this patient had aberrant mitochondrial elongation. Drp1 mainly localizes in the cytosol, and during mitochondrial fission, translocates from the cytosol to prospective fission sites on the mitochondria (Figure 4) (Smirnova *et al.*, 2001). *In vitro* studies as well as studies of yeast Dnm1 revealed that Dnm1 or Drp1 assembles, like dynamin, into higher-order structures that wrap around the mitochondrial tubule (Smirnova *et al.*, 2001; Yoon *et al.*, 2001; Ingeman *et al.*, 2005). These spiral-shaped higher-order structures are thought to constrict and eventually sever the mitochondrial membrane by a GTP hydrolysis-dependent mechanism. Time-lapse imaging of GFP-tagged Drp1 shows that mitochondrial tubules divide at sites where these punctate structures are found (Smirnova *et al.*, 2001). The GTP-binding defective mutant (K38A) sequesters endogenous Drp1 into uncharacterized aggregated or dotted structures, thus inhibiting its localization on the mitochondrial fission sites to act as a dominant-negative mutant (Smirnova *et al.*, 2001; Yoon *et al.*, 2001). Intermolecular interactions between the N-terminal GTPase domain and C-terminal GED are also important for Drp1 self-assembly and functional regulation (Zhu *et al.*, 2004). The regulation of MIM scission as well as the mechanisms synchronizing scissions of the MIM and MOM are not yet known. The MIM-localized MTP18 is a transcriptionally regulated target of the phosphatidylinositol 3-kinase signaling and regulates mitochondrial fission coupled with the action of Drp1 at the MOM (Tondera *et al.*, 2005). Depletion and overexpression of MTP18 promote mitochondrial elongation and fragmentation, respectively, indicating its role in the regulation of mitochondrial fission. The identification of its interacting partners will help to understand the molecular mechanisms that synchronize MIM and MOM scission.

Key Players on the MOM in Drp1-Dependent Mitochondrial Fission: Mff, Mid49, and Mid51/MIEF1

Despite extensive studies, the mechanisms by which the cytoplasmically localized Drp1 is activated and recruited to the

prospective mitochondrial fission sites remain unclear. Cell biologic and genetic studies recently identified three MOM proteins involved in Drp1-dependent mitochondria fission, mitochondrial fission factor (Mff) and mitochondrial dynamics protein of 49- and 51-kDa (Mid49 and Mid51; also named mitochondrial elongation factor 1 (MIEF1) for Mid51) (Figure 4). Mff is a C-tail anchored protein on the MOM that was first identified in a *Drosophila* RNAi library search for mitochondrial morphology alterations (Gandre-Babbe and van der Bliek, 2008). Mammalian mitochondria contain an Mff ortholog and silencing this factor by RNAi induces mitochondrial elongation in mammalian cells. The specific role of Mff in mitochondrial fission, however, remains unknown. We demonstrated that (1) Mff RNAi affects the mitochondrial recruitment of Drp1. Endogenous Drp1, observed as dotted structures on mitochondria, was clearly decreased and dispersed in the cytoplasm in Mff RNAi cells, concomitant with mitochondrial network extension and acquisition of resistance to apoptotic stimuli. (2) In contrast, Mff overexpression induces mitochondrial fragmentation, concomitant with increased Drp1 recruitment to the mitochondria and increased apoptotic sensitivity. (3) Consistent with these observations, both *in vitro* and *in vivo* experiments demonstrated that Mff transiently interacts with Drp1 through its N-terminal cytoplasmic region. Furthermore, (4) Mff mostly colocalizes with the Drp1 foci on the MOM in marked contrast to the uniform localization of hFis1 in the MOM. (5) Of note, conditional knockout of hFis1 in colon carcinoma cells revealed that it is dispensable for mitochondrial fission. These observations indicate that Mff functions as a Drp1 receptor on the MOM to mediate mitochondrial fission (Otera *et al.*, 2010).

Mid49 and Mid51/MIEF1 were identified by random cellular localization screening of uncharacterized human proteins for unique changes in mitochondrial distribution and morphology (Palmer *et al.*, 2011; Zhao *et al.*, 2011). Mid49 and Mid51/MIEF share 45% sequence identity and specifically localize to mitochondria, but not to peroxisomes, and anchor to the MOM through N-terminal TMs exposing bulk C-terminal segments to the cytoplasm (Figure 4). Mid49 and Mid51 form foci and rings around mitochondria and can act independently of Mff in Drp1 recruitment and are specific for mitochondrial fission. Overexpression of Mid49 and Mid51 inhibits Drp1 function by acting in a dominant-negative manner to sequester Drp1 specifically at mitochondria, leading to unopposed fusion of mitochondria and peroxisomes. This elongation depends on the unopposed function of Mfn1 and Mfn2, thus indicating that the Mid proteins are not fusion factors; marked contrast to the suggested function for MIEF (Zhao *et al.*, 2011). In contrast to Fis1 and Mff, Mid49/Mid51 is not targeted to peroxisomes or lysosomes; although when artificially targeted using a peroxisomal- or lysosomal-targeting signal, Drp1 is specifically recruited to these organelles (Palmer *et al.*, 2013). The Drp1 recruitment activity appeared stronger than that of Mff. In contrast to the overexpression effect, different knockdown phenotypes were reported by two laboratories. Ryan and colleagues reported that knockdown of either Mid49 or Mid51 had no effect on mitochondrial morphology, but simultaneous knockdown of both induced mitochondrial elongation. In contrast, Nister and colleagues reported that knockdown of Mid51/MIEF induces

mitochondrial fragmentation, leading to the conclusion that Mid51/MIEF recruits Drp1 to the MOM and promotes mitochondrial fusion rather than fission. Experiments with receptor-specific KO cells will be required to resolve these inconsistencies.

The crystal structure of the cytoplasmic domain of human Mid51 was recently solved by X-ray crystallography (Richter *et al.*, 2014; Loson *et al.*, 2014). It contains a variant of the nucleotidyl transferase domain (NT) that binds ADP in the middle part of the molecule (Richter *et al.*, 2014; Loson *et al.*, 2014), and the surface-exposed Drp1 recruitment loop (DRR) (Figure 4). Mid51 is present as a dimer and ADP binding does not affect its oligomeric state or Drp1 binding. Strikingly, experiments both *in vivo* and *in vitro* with the ADP-binding mutant or dimerization mutant revealed that Mid51 is competent for Drp1 recruitment irrespective of the presence or absence of ADP, but its potential for ADP binding and dimerization is essential for Drp1 activation by stimulating oligomeric assembly of Drp1 on the mitochondrial surface in response to fission-stimulating signals (Loson *et al.*, 2014). Thus, ADP is essential for Mid51 function during mitochondrial fission. Of note, Mid49 has an only partially conserved nucleotidyl transferase domain and the function is not regulated by ADP (Loson *et al.*, 2014).

Drp1 might self-assemble via its ability to homo-oligomerize on Mff, Mid49, or Mid51 of the mitochondrial surface, forming spiral structures around the mitochondrial tubules. After this process, unidentified Mff- or Mids-interacting factors might affect the assembly and activation of the fission machinery, leading to membrane constrictions or lipid remodeling and eventually to membrane scission. In yeast, the MOM protein Fis1 functions as the fission receptor for Dnm1 via adapter proteins Mdiv1/Caf4. In contrast to the conservation of Fis1 through various species, there are no obvious homologs of yeast fission adapters Mdiv1/Caf4 in metazoans. Mammalian mitochondria seem to adopt fission mechanisms that are distinct from those of yeast or plants. As discussed in the following section, mammalian Fis1 does not appear to be directly involved in mitochondrial fission as a Drp1 receptor.

The capacity of the above-mentioned adapter proteins to recruit Drp1 was elegantly analyzed by Shaw's group in yeast strains lacking all fission proteins, which revealed that cytoplasmic domains of Mff or Mids targeted to the yeast MOM by the respective MOM-targeting signal are sufficient to recruit human Drp1 to yeast mitochondria, facilitating Drp1's oligomeric assembly around constriction sites to eventually catalyze mitochondrial fission, although human Fis1 failed to both recruit Drp1 and induce mitochondrial fission in this assay system (Koirara *et al.*, 2013).

What is the functional division of DRP1-daptor proteins Mff, Mid49, and Mid51 in the Drp1-dependent mitochondrial fission reaction? Studies to date have not identified significant differences in the mitochondrial fission events mediated by these adapters except for the overexpression phenotype; Mid proteins, but not Mff, exhibit a dominant-negative effect on mitochondrial fission (Otera *et al.*, 2010; Palmer *et al.*, 2011; Zhao *et al.*, 2011). Posttranslational modifications of Drp1, including phosphorylation, sumoylation, nitrosylation, and ubiquitination (see Section Regulation of Drp1 by Post-translational Modifications), could influence the identity of

the adapters, or these modifications of the adapters could regulate the function of the adapters themselves. Another possibility is that multiple adapters work together with Drp1 as a single division machinery.

How are future mitochondrial fission sites determined? Immuno-electron microscopy and time-lapse fluorescence microscopy in yeast and mammalian cells showed that Dnm1/Drp1 colocalizes with constrictions on the presumed future mitochondrial fission sites (Mozdy *et al.*, 2000; Smirnova *et al.*, 2001). Three-dimensional time-lapse fluorescence imaging revealed that constriction formation and Dnm1 recruitment as patches or ring structures are distinct processes (Legesse-Miller *et al.*, 2003). So, how are future fission sites selected? Friedman and colleagues addressed this problem with electron microscopy and live cell fluorescence microscopy in yeast and mammalian cells, and demonstrated that the ER wraps around mitochondria and mediates constrictions, where Mff accumulation and subsequent Drp1 recruitment proceed (Friedman *et al.*, 2011; Friedman and Nunnari, 2014). The ER-bound form of inverted formin (INF2) is reported to be involved in this process; INF2 accumulates at the ER-mitochondria contact sites, where INF2 promotes actin polymerization and myosin II accumulation to produce constrictions, thus enhancing the subsequent accumulation of Drp1 and fission (Korobova *et al.*, 2013; Korobova *et al.*, 2014; Figure 5).

Modulators of Mitochondrial Fission

Fis1

Fis1 is a C-tail anchored MOM protein with its N-terminal multiple tetratricopeptide repeat motif exposed to the cytoplasm (Yoon *et al.*, 2003). In yeast, Fis1 is required for Dnm1 recruitment. During mitochondrial fission, Fis1 transiently interacts via cytosolic adapter proteins Mdiv1/Caf4 with Dnm1 by its tetratricopeptide repeat motif, suggesting its function as a mitochondrial Dnm1 receptor (Lackner *et al.*, 2009). In mammals, Fis1 has also been identified in mitochondria (hFis1 for human Fis1) and is thought to be involved in recruiting Drp1 to mitochondria, as in yeast, through direct or indirect interactions (Yoon *et al.*, 2003). The actual function of hFis1, however, remains enigmatic, because Mdiv1/Caf4-like adapter proteins have not been identified, hFis1 localizes throughout the MOM unlike the punctate localization of Drp1, and mitochondrial recruitment of Drp1 is not affected by hFis1-knockdown (Otera *et al.*, 2010). TBC1D15, a Rab GTPase-activating protein (Rab-GAP), is a binding partner of hFis1, and furthermore TBC1D15 and another TBC family member TBC1D17 participate with hFis1 in autophagic encapsulation of damaged mitochondria in a later step of Parkin-PINK dependent mitophagy (Onoue *et al.*, 2013; Yamano *et al.*, 2014). Considering that Drp1 is involved in the early steps of mitophagy to segregate disintegrated mitochondria for degradation (Twig *et al.*, 2008), direct involvement of hFis1 in the regulation of Drp1 function seems to be very low.

Ganglioside-induced differentiation-associated protein 1 (GDAP1)

GDAP1 is another mitochondrial fission-related factor located on the MOM through a C-terminal hydrophobic

Figure 5 Endoplasmic reticulum (ER)-assisted mitochondrial fission. Speculative process of mitochondrial fission at the mitochondria-ER contact sites. The ER-bound form of inverted formin (INF2) wraps around mitochondrial tubules, and induces actin polymerization and myosin II accumulation to produce membrane constrictions, where adaptor proteins Mff and Mids (small green rods) accumulate to mediate Drp1 recruitment and its ring-like oligomeric assembly. GTP hydrolysis-mediated contractile force drives mitochondrial fission.

transmembrane domain extruding the bulk of the N-terminal domain into the cytoplasm (Niemann *et al.*, 2005). GDAP1 is involved in ganglioside maturation. Mutations in GDAP1 lead to the peripheral neuropathy Charcot-Marie-Tooth (CMT) disease, which affects Schwann cells, myelinating glia in the peripheral nervous system, and neurons (Cassereau *et al.*, 2011). Although it is not clear how GDAP1 is involved in mitochondrial fission, these data suggest the importance of membrane lipid compositions such as gangliosides in mitochondrial fission. GDAP1 mutants found in patients with CMT disease are not targeted to the mitochondria and lack mitochondrial fragmentation activity (Niemann *et al.*, 2005). GDAP1-induced mitochondrial fragmentation is inhibited by Drp1 knockdown or expression of the dominant-negative Drp1-K38A mutant, indicating that GDAP1 is a Drp1-dependent regulator of mitochondrial fission (Niemann *et al.*, 2005). Huber *et al.* (2013) recently reported that GDAP1 is also targeted to peroxisomes by the action of peroxisomal import receptor Pex19 and mediates Drp1- and Mff-dependent peroxisomal fission, as in mitochondrial fission. GDAP1 has two glutathione-S-transferase family domains and over-expression of wild-type GDAP1, but not CMT disease mutants, increases cellular glutathione levels and the mitochondrial membrane potential, although the functional relation to mitochondrial morphology regulation remains unknown (Noack *et al.*, 2012).

Endophilin B1/Bif-1

Endophilin B1 (also known as Bax-interacting factor 1, Bif-1) is a fatty acyl transferase mainly localizing in the cytoplasm that regulates mitochondrial morphology and MOM dynamics acting downstream of Drp1, probably through lipid remodeling of the MOM. Knockdown of endophilin B1 induces unusually interconnected or extended mitochondrial tubules, several of which have bleb-like structures (Karbowski *et al.*, 2004). This manipulation induces the dissociation of MOM and MIM compartments, suggesting that endophilin B1 is required for maintenance of MOM and MIM synchronous morphogenesis. Epistatic studies using cells subjected to single and double knockdown of Drp1 and endophilin B1 revealed

that Drp1 acts upstream of endophilin B1 in the maintenance of mitochondrial morphologic dynamics. Upon the induction of apoptosis, endophilin B1 is recruited from the cytoplasm to the mitochondria as punctate structures, where it interacts transiently with Bax oligomers, and promotes cytochrome c release from the mitochondria (Karbowski *et al.*, 2004; Rostovtseva *et al.*, 2009). The mechanism and physiologic function of Drp1-dependent mitochondrial recruitment of endophilin B1 require further analysis, although it is proposed to have a role in autophagosome formation (Takahashi *et al.*, 2009).

Sacsin

Sacsin is a 520-kDa protein encoded by the SACS gene, whose mutations cause childhood-onset autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS; Anderson *et al.*, 2010). At the N-terminus, Sacsin contains a ubiquitin-like domain, which is followed by three Sacsin Repeat Regions that possess ATPase activity, a 75-residue XPC-binding domain implicated in interactions with ubiquitin ligase Ube3A, a DNA J-like domain, and a HEPN (higher eukaryotes and prokaryotes nucleotide-binding) domain with an affinity for GTP. It is highly expressed in the central nervous system, and is also found in the skin, skeletal muscles, and, at low levels, in the pancreas. Recent work indicates that Sacsin is localized to the mitochondria, partially overlapping with the Drp1 foci (Giard *et al.*, 2012). Exogenously expressed Sacsin (1–1368 residue segment) interacts with endogenous Drp1. Interestingly, mitochondria in the cells of Sacsin-KO mice and in patients with the autosomal recessive spastic ataxia of Charlevoix-Saguenay display a hyperfused balloon-like mitochondrial morphology, mimicking the characteristic mitochondrial structures observed in Drp1- or Mff-knockdown cells or in dominant-negative Drp1-K38A-expressing cells. In sacsin-deficient neuronal cells, enlarged mitochondria are clustered and accumulate in the soma and proximal dendrites, and display fewer dendrites than control cells, a morphologic response observed in the neuronal cells of Drp1 KO mice (see below). Importantly, Sacsin-KO mice exhibit an age-dependent loss of cerebellar Purkinje cells, probably due to disturbances in the

mitochondrial delivery within neurites (Giard *et al.*, 2012). These findings suggest that Sacsin regulates Drp1 activity with a speculated function of chaperon activity.

Listeria toxin (LLO)

Of note, a Drp1-independent, atypical mitochondrial fission mode has been reported. *Listeria monocytogenes*, a food-borne pathogen capable of invading nonphagocytic cells, causes fragmentation of the host mitochondria by its pore-forming toxin LLO (55-kDa) before bacterial entry (Stavru *et al.*, 2013). A small dose of LLO efficiently induces mitochondrial fragmentation concomitant with transient dissipation of mitochondrial membrane potential, respiration, and cellular ATP levels. This seems to be an elaborate strategy of pathogens to induce transient shutdown of mitochondrial function to interfere with the host physiology. Interestingly, recombinant LLO induces the degradation of Mff concomitantly with the release of Drp1 from mitochondria to the cytoplasm and strong mitochondrial fragmentation. Moreover, it induces efficient mitochondrial fragmentation both in Drp1 KO MEF and Mff-KO HCT116 cells. Surprisingly, the ER and F-actin also have active roles in regulating LLO-induced mitochondrial fission, suggesting that this fission reaction partly shares the pathway with Drp1-dependent mitochondrial fission (Stavru *et al.*, 2013).

Regulation of Drp1 by Posttranslational Modifications

Various stressors outside or inside cells induce mitochondrial fission to remodel mitochondria and cellular functions. During apoptosis, cytoplasmic Drp1 is translocated to the mitochondria and induces mitochondrial fragmentation prior to caspase activation by the release of cytochrome *c* (Frank *et al.*, 2001). Such increased fission events are also important for autophagic clearance of depolarized (or dysfunctional) mitochondria or for proper segregation of mitochondria into daughter cells during mitosis (Twig *et al.*, 2008). Overexpression of wild-type Drp1 does not lead to mitochondrial fragmentation, suggesting that a simple alteration of Drp1 levels does not change mitochondrial fission but the regulation of Drp1 properties, such as mitochondrial recruitment, higher-order assembly, or GTPase activity is rather critical. In this context, posttranslational modifications are implicated as regulatory mechanisms during mitochondrial fission (Figure 4).

Phosphorylation

During mitosis, rat Drp1 is activated by Cdk1/cyclin B-mediated phosphorylation of Ser585 (Ser616 for human Drp1) in the GED. This mitotic phosphorylation promotes Drp1-dependent mitochondrial fission and facilitates proper distribution and segregation of mitochondria into the daughter cells (Taguchi *et al.*, 2007). The exact mechanisms linking Drp1 phosphorylation at Ser585 to increased fission activity remain to be determined. A serine residue within the GED (Ser637 for human Drp1; Ser656 for rat Drp1) is phosphorylated by protein kinase A in HeLa and PC12 cells. This phosphorylation inhibits mitochondrial fission through inhibition of the intramolecular interaction between the GTPase domain and the GED, GTPase activity, and eventually mitochondrial

recruitment of Drp1 (Chang and Blackstone, 2007). In this context, calcineurin dephosphorylates Ser637 and stimulates Drp1 translocation to the mitochondria (Cribbs and Strack, 2007; Cereghetti *et al.*, 2008). For example, poly-glutamine expansions in Huntingtin protein, the cause of Huntington's disease, superactivates calcineurin through enhanced calcium levels, and increases mitochondrial recruitment of Drp1 (Cereghetti *et al.*, 2008). Furthermore, mutant Huntingtin protein directly binds Drp1 and increases its GTPase activity, leading to mitochondrial fragmentation and defects in anterograde and retrograde mitochondrial transport (Song *et al.*, 2011). In contrast, Ca^{2+} signaling activates Ca^{2+} /calmodulin-dependent protein kinase $\text{I}\alpha$ to phosphorylate Ser637 and increases mitochondrial translocation of Drp1 by increasing the Drp1 binding affinity for hFis1 in hippocampal neurons (Han *et al.*, 2008). Thus, phosphorylation of Drp1 at the same GED residues is likely to have opposite effects on the mitochondrial fission activity in different cells or tissues. Ca^{2+} /calmodulin-dependent protein kinase 1a also mediates phosphorylation of Ser600 in human Drp1 isoform 3 (corresponding to Ser637 in human Drp1 isoform 1), which induces mitochondrial fragmentation during voltage-dependent Ca^{2+} signaling in cultured hippocampal neurons (Han *et al.*, 2008). The mechanistic background of these opposite effects remains to be investigated.

O-GlcNacylation

Gawlowski *et al.* (2012) recently demonstrated O-GlcNacylation at Thr-585 and Thr-586 in the insert B-domain (VD) of Drp1 in rat neonatal cardiac myocytes; the reaction was significantly augmented by the inhibition of N-acetyl-glucosaminidase, leading to elevated levels of GTP-bound active Drp1, its mitochondrial translocation, and the induction of mitochondrial fragmentation. The reaction was also stimulated upon shifting cells from low to high glucose medium, concomitant with an increase in the Drp1 expression level. Interestingly, this reaction paralleled a decrease in Ser637-phosphorylated Drp1, resulting in the mitochondrial recruitment of Drp1. The reaction was detected for cardiac Drp1 in a mouse model of type 2 diabetes, and therefore, might be linked to the development of diabetes-induced mitochondrial dysfunction and cardiovascular complications.

S-Nitrosylation

S-Nitrosylation is a ubiquitous protein modification in redox-based signaling. β -Amyloid protein, a key mediator of Alzheimer's disease, stimulates nitric oxide production to cause S-nitrosylation of human Drp1 at Cys644 within the GED, which enhances GTPase activity and Drp1 oligomer formation in association with excessive mitochondrial fission in neurons, leading to synaptic loss and neuronal damage in the brains of patients with Alzheimer's disease (Cho *et al.*, 2009), although this model has been challenged (Bossy *et al.*, 2010). A mutation of Cys644 prevents mitochondrial fragmentation and blocks the neurotoxicity induced by nitric oxide or β -amyloid protein (Cho *et al.*, 2009).

SUMOylation

The small ubiquitin-like modifier (SUMO) protein also affects Drp1 activity. Overexpression of SUMO1 stabilizes Drp1 in a

Bax/Bak-dependent manner on the mitochondrial membrane and induces mitochondrial fission, suggesting that sumoylation is a step in Drp1 regulation during early apoptosis progression (Wasiak *et al.*, 2007). Mitochondrial SUMO E3 ligase (MAPL) has been identified as SUMO E3 ligase for Drp1 (Braschi *et al.*, 2009). Conversely, overexpression of the Sumo protease SENP5 decreases Drp1 sumoylation and rescues SUMO1-induced mitochondrial division (Zunino *et al.*, 2007). Neuspiel *et al.* (2008) reported that MAPL is incorporated in previously uncharacterized mitochondria-derived vesicles (MDVs) that bud from mitochondria and are transported to peroxisomes. Communication with peroxisomal membranes might thus influence mitochondrial morphology or lipid biosynthesis (Braschi *et al.*, 2010).

Ubiquitination

In addition to SUMOylation, ubiquitination regulates Drp1 activity. A mitochondria-associated RING-finger E3 ubiquitin ligase, MARCH5 (also known as MITOL) ubiquitinates Drp1 on the MOM, although the effect of MARCH5/MITOL-dependent ubiquitination of Drp1 on mitochondrial dynamics remains controversial. MARCH5/MITOL silencing or overexpression of the MARCH5/MITOL mutant lacking ubiquitin ligase activity induces mitochondrial fragmentation (Nakamura *et al.*, 2006; Yonashiro *et al.*, 2006). Karbowski *et al.* (2007), however, later demonstrated that MARCH5/MITOL silencing, as well as overexpression of the RING-inactive MARCH5/MITOL mutant, induces abnormal mitochondrial accumulation of Drp1 in association with abnormal mitochondrial elongation and their interconnections. In addition, MARCH5/MITOL might have a more general role in the quality control of mitochondria by ubiquitination and removal of mutated, damaged, or misfolded protein accumulated in the MOM, as observed for a mutated version of superoxide dismutase or expanded poly-Q proteins (Sugiura *et al.*, 2011). Of note, as described already in part II-2, MARCH5/MITOL is also involved in the regulation of mitochondria-ER tethering by ubiquitinating the mitochondria-bound form of Mfn2. Thus, whether and how MARCH5/MITOL contributes to mitochondrial dynamics is an important issue for future studies. Different effects induced by the same modification might depend on circumstances such as where and when the effects occur within the cells or the cell type. Although the exact mechanism of Drp1 regulation via the above-mentioned modifications is unclear, it is likely that posttranslational modifications of Drp1 both positively and negatively regulate its function in mitochondrial dynamics.

Interaction with cardiolipin

Cardiolipin is the principal phospholipid of the mitochondrial membrane and is implicated in mitochondrial dynamics, affecting the MOM and MIM structures during various processes. In fact, coassembly of s- and l-Mgm1 proceeds in *trans* in a cardiolipin-dependent manner (DeVay *et al.*, 2009). In mammalian Opa1, a low basal GTPase activity is dramatically enhanced by an association with negatively charged phospholipids such as cardiolipin, which triggers the assembly of Opa1 into higher-order oligomers (Ban *et al.*, 2010). In a similar vein, *in vitro* analysis of Drp1 function in apoptosis revealed that Drp1 stimulates tBid-induced Bax oligomeri-

zation in a cardiolipin-dependent manner; Drp1 catalyzes the formation of a hemi-fusion/fission intermediates in a cardiolipin-dependent manner (Montessuit *et al.*, 2010). *In vitro*, cardiolipin potently binds to Drp1 and activates GTPase, leading to membrane tubulation to a diameter (100–150 nm) similar to that at the mitochondrial constriction site (Macdonald *et al.*, 2014). Considering that the cardiolipin is enriched at the MOM-MIM contact sites (Tatsuta *et al.*, 2014), the cardiolipin-enriched microdomains might constitute the sites of Drp1 recruitment. If this is the case, how cardiolipin shares receptor function with Mff and Mid49/Mid51 *in vivo* remains an important question.

Physiologic Importance of Mitochondrial Dynamics

Mfn1-, Mfn2-, and Opa1-Dependent Mitochondrial Fusion

Chan and colleagues generated Mfn1- and Mfn2-KO mice (Chen *et al.*, 2003). In contrast to the full viability of heterozygous animals, homozygous mutants are embryonic lethal. Mfn1-KO mice were embryonic lethal by embryonic day 12.5 (86% mutant embryos are resorbed). Similarly, 87% of Mfn2-KO embryos were resorbed by embryonic day 11.5. Mfn1 and Mfn2 double-KO embryos died earlier than either single mutants and showed greater developmental delay, indicating that Mfn1 and Mfn2 are both required and have a cooperative relationship in developmental events early in embryogenesis. The placental trophoblast giant cell layer was specifically and severely disrupted in Mfn2-KO mice, whereas they were normal in Mfn1-KO mice, suggesting a functional *in vivo* difference between Mfn1 and Mfn2. Mfn1-KO and Mfn2-KO mutant culture cells contained mitochondria with a depolarized membrane potential, indicating that while bulk cultures display respiratory activity, the function of individual mitochondria is compromised in the absence of either Mfn1 or Mfn2.

As discussed above, Mfn2 has critical roles not only in mitochondrial fusion, but also in the establishment of mitochondria-ER interactions (de Brito and Scorrano, 2008). In this context, Zorzano and colleagues, using liver-specific and skeletal muscle-specific Mfn2-KO mice, demonstrated that Mfn2 coordinates mitochondria and ER function to modulate metabolism; Mfn2 deficiency causes ER stress, mitochondrial dysfunction, and an increase in hydrogen peroxide, leading to altered insulin signaling and glucose intolerance in cells, which were ameliorated by chemical chaperones and the antioxidant N-acetylcysteine (Sebastian *et al.*, 2012). Similarly, Schneeberger *et al.* (2013) reported that mitochondrial network complexity and their association with the ER in anorexigenic pro-opiomelanocortin (POMC) neurons of the hypothalamus, major targets of leptin action, are decreased in mice with diet-induced obesity. Depletion of Mfn2, but not Mfn1, in POMC neurons results in various cellular defects, such as reduced POMC processing to α -melanocyte-stimulating hormone, reduced mitochondria-ER contacts, reduced mitochondrial respiration, enhanced ROS production, and development of leptin resistance, eventually causing severe obesity. Further, inhibition of ER stress in the hypothalamus by chemical chaperone treatments reverses these phenotypes

of POMC-Mfn2-KO mice. Thus, the mitochondria-ER contact regulated by Mfn2 in POMC neurons plays a crucial function in mediating ER-induced leptin resistance, and is an essential regulator of the whole-body energy balance.

On the other hand, [Dietrich et al. \(2013\)](#) analyzed mitochondrial dynamics in orexigenic agouti-related protein (Agrp) neurons during various metabolic states and assessed the role of Mfn1 and Mfn2 in these processes using Agrp Mfn1-KO and Agrp Mfn2-KO mice. They demonstrated that mitofusin deficiency impairs the action potential frequency of Agrp neurons in response to a high-fat diet and the KO mice gained less weight when fed a high-fat diet. Of note, in contrast to the case of anorexigenic POMC neurons, the depletion of Mfn proteins did not lead to a decrease in ER-mitochondria connections or an increase in ER stress, indicating divergent roles for Mfn proteins in a cell-type-specific manner ([Dietrich et al., 2013](#)). Together these experiments revealed critical roles of Mfn1 and Mfn2 in the regulation of the metabolic response of Agrp neurons. In addition to the role of mitochondrial fusion in tissue homeostasis, its role in the regulation of cellular differentiation has been clarified. Scorrano and colleagues demonstrated that heart-specific Mfn1-KO or Mfn2-KO mice, and gene-trapping of Mfn2 or Opa1 in mouse embryonic stem cells arrested mouse heart development and impaired differentiation of embryonic stem cells into cardiomyocytes, revealing the presence of a mitochondrial fusion-sensitive Ca^{2+} /calcineurin pathway that directs cardiomyocyte differentiation through Notch signaling ([Kasahara et al., 2013](#)). As discussed above, OMA1 mediates stress-induced processing of L-Opa1 at the S1 site. [Quiros et al. \(2012\)](#) generated OMA1-KO mice and analyzed their phenotype. The mice develop normally, with males and females being fertile, and their survival rates are indistinguishable from those of the wild-type littermates. At the cellular level, as confirmed in previous reports, stress-induced conversion of L-Opa1s to S-forms is completely blocked in OMA1-KO cells, and correspondingly, the cells have highly connected and less-fragmented mitochondria that are resistant to dissipation of the mitochondrial membrane potential by CCCP treatment ([Quiros et al., 2012](#)). Furthermore, mitochondria in OMA1-KO cells have a tight structural organization of cristae junctions and are resistant to proapoptotic reagents. Of note, the mutant cell mitochondria have decreased mtDNA levels, suggesting that Opa1 functions to maintain mtDNA. Interestingly, OMA1 ablation leads to a marked upregulation of genes related to lipid metabolism and metabolic pathways related to the obesity phenotype, and mutant mice exhibit a progressive increase in body weight compared with control mice; these effects are enhanced when the mice are maintained on a high-fat diet. These experiments revealed that the precise balance between L-Opa1 and S-OMA1 regulated by OMA1 is essential for metabolic homeostasis ([Quiros et al., 2012](#)).

Drp1-Dependent Mitochondrial Fission

To elucidate the detailed physiologic roles of mitochondrial fission *in vivo*, we and another group generated tissue-specific Drp1 KO mice using the Cre and loxP system ([Ishihara et al., 2009](#); [Wakabayashi et al., 2009](#)). Although Drp1 is dispensable

for murine embryonic fibroblast (MEF) viability, Drp1 KO mice die at around embryonic day 12.5 due to developmental abnormalities, particularly in the forebrain. In addition, a missense mutation in mouse Drp1 in the middle domain that is essential for intramolecular interactions (Python mice; C452F mutation) leads to cardiomyopathy ([Ashrafian et al., 2010](#)). The main developmental abnormalities observed in Drp1 KO mice are defects in the forebrain and synapse development, poorly developed livers, and compromised cardiac formation or function ([Ishihara et al., 2009](#); [Wakabayashi et al., 2009](#)), while heterozygous Python mice exhibit depletion of cardiac ATP and cardiomyopathy ([Ashrafian et al., 2010](#)). To date, only a dominant-negative middle domain mutation (A395D) in Drp1 has been reported in a lethal disorder with microcephaly, abnormal brain development, optic atrophy, hypoplasia, persistent lactic acidemia, and a mildly elevated plasma concentration of very-long-chain fatty acids ([Waterham et al., 2007](#)). Despite its severe clinical phenotype, respiratory-chain enzyme activities are normal in muscle and in cultured fibroblasts derived from the patient. Neurons are particularly vulnerable to mitochondrial dysfunction. Neuron-specific Drp1 KO mice are viable at birth, but quickly die due to neurodegeneration ([Ishihara et al., 2009](#); [Wakabayashi et al., 2009](#)). In primary cultured neural cells from Drp1 KO embryos, enlarged and aggregated mitochondria are sparsely distributed in the neurites, and the synaptic structures are lost ([Ishihara et al., 2009](#); [Wakabayashi et al., 2009](#)). These findings suggest that Drp1 deficiency causes an abnormal distribution of enlarged mitochondria in extremely polarized cells such as neurites; these spatiotemporal defects may inhibit the ATP supply and Ca^{2+} signaling, eventually preventing synapse formation. Taken together, these results suggest that Drp1 deficiency results in unusually shaped, large mitochondria with compromised intracellular movement, which leads to neuronal cell death. Mitochondrial fission also functions as a quality control system to suppress age-dependent oxidative damage and thus promote neuronal survival ([Twig et al., 2008](#); [Chan, 2012](#); [Archer, 2013](#)). Determining the physiologic relevance of Drp1 in other tissues that might underlie various human diseases remains to be addressed.

Mitochondrial fission is a physiologic response in brown adipose tissue. Brown adipose tissue is an important site for energy expenditure, and cold exposure and adrenergic stimulation induce heat generation preceded by rapid mitochondrial fragmentation. Shrihail and colleagues recently demonstrate that cold exposure or norepinephrine-stimulation activates Drp1 by PKA-dependent Ser600 phosphorylation to induce mitochondrial fragmentation as an essential step of heat generation ([Wikstrom et al., 2014](#)). This fragmentation enhances uncoupling of oxidative phosphorylation in mitochondria by free fatty acids that are generated through different pathways, leading to heat production in brown adipose tissue.

Perspective

Recent advances in live cell imaging revealed that mitochondria are highly dynamic through continuous fusion and

fission, as well as movement along the cellular cytoskeleton. Mitochondrial fusion and fission have important roles not only in the modulation of mitochondrial morphology, but also in other biologic processes, including bioenergetics, cellular metabolism, mitochondrial maintenance, synaptic integrity, and neuronal cell death. Over the past decade, despite the accumulation of a significant amount of data regarding the identification of proteins modulating mitochondrial dynamics and their molecular function, characterization of the coordination and regulation of these proteins remains in a preliminary stage. Several fundamental questions, such as the exact role of the mitochondrial shape proteins and the coordination of fusion and fission, are unsolved. A number of studies demonstrated that mitochondrial morphology and its physiologic functions differ depending on the cell-type or tissue. These variations and the cell-type specificity of mitochondrial dynamics might be related to specific cellular functions, such as in neurons. Therefore, learning how and the degree to which mitochondrial dynamics influence cell-specific functions in various tissues continues to be a challenging task. Future research to investigate the complex crosstalk between mitochondrial dynamics and their physiologic function are likely to provide exciting breakthroughs in the fields of cell biology and for clinical medicine.

Synaptosomes and Synaptic Vesicles

Introduction

This article describes the composition and cell biology of both synaptosomes and synaptic vesicles (SVs). Synaptosomes are biochemically isolated structures that consist of pinched-off nerve terminals, the juxtaposed postsynaptic density, and any associated extracellular matrix proteins that link the two. Synaptosomes are generated during homogenization of brain tissue under iso-osmotic conditions and can be considered as pseudo-organelles because the neck of the axon terminal spontaneously seals up upon homogenization. They were first isolated by Hebb and Whittaker in 1957 (Hebb and Whittaker, 1958), although a clear understanding of their nature was not known until their fine structure was determined using electron microscopy (Gray and Whittaker, 1960), and the term 'synaptosome' itself was not used to describe such structures until 1964 (Whittaker *et al.*, 1964). Because the isolated axon terminal is membrane-bound, synaptosomes are functionally active in the sense that they can respond to depolarizing conditions, which mimic invasion of an action potential into the terminal. In the presence of glucose and oxygen-containing media, they are able to maintain near physiological levels of ATP, which allows for kinase-based signal transduction. There are four criteria that synaptosomes must meet: the axon terminal portion must have resealed, this enclosed region must contain one or more mitochondria, a large fraction of the initial synaptic vesicle pool must be present, and a significant portion of the initial postsynaptic density must still be opposed to the presynaptic active zone. The initial iso-osmotic homogenization may leave the overall postsynaptic spine mostly intact, or substantially removed (Whittaker, 1965).

SVs are small, membrane-enclosed structures, which range from ten to hundreds of copies, that are present in axon terminals of chemical synapses. They are filled with neurotransmitter, and the particular neurotransmitter they contain varies as a function of synaptic type. During neurotransmission, an action potential invades the presynaptic terminal, which causes depolarization of the plasma membrane. This depolarization activates voltage-gated calcium channels that are positioned close to a subset of vesicles in a specialized region of the axon terminal known as the active zone. The resulting calcium influx is sensed by specific proteins on the surface of SVs. Calcium binding by these proteins acts as a trigger for a protein complex that mediates fusion of SVs with the plasma membrane, releasing neurotransmitter into the synaptic cleft. These neurotransmitter molecules diffuse across the cleft and activate specific receptors on the surface of the postsynaptic cell, thereby propagating the neuronal signal. SVs can be biochemically isolated from the brain, and synaptosome preparations are an intermediate step in their enrichment.

Synaptosomes

The synaptosome fraction is generally isolated using density centrifugation, and several approaches have been developed for its purification. The initial brain homogenate is first centrifuged in order to pellet the so-called 'P1' fraction, which consists of nuclei, tissue debris, and large fragments of myelin sheath. The supernatant 'P2' fraction is then subjected to another round of centrifugation using a continuous or discontinuous sucrose gradient, Ficoll or Percoll (Booth and Clark, 1978; Nagy and Delgado-Escueta, 1984). This yields a fraction highly enriched for synaptosomes and depleted of free mitochondria. Synaptosomes possess all those components present in the original axon terminal. These include SVs; large dense core vesicles, mitochondria, synaptic active zones, proteins of the postsynaptic density, and associated signaling machinery, as well as any cytoplasmic proteins present at the synapse.

While the efficiency of synaptosome generation will vary with terminal spine geometry as well as the degree to which shearing forces are applied during homogenization, synaptosomes have been isolated from most neural tissues with similar efficiencies, with the slight exception of large mossy-fiber nerve terminals in the cerebellum that generate synaptosomes at poor yield (Israel and Whittaker, 1965). Therefore, synaptosomes generated from the whole brain will contain a representation of all synaptic types present in the starting material, including both excitatory and inhibitory synapses. In general, multiple synapse types are tightly co-distributed throughout the brain, and therefore microdissection is unlikely to yield highly homogeneous populations of synaptosomes.

The protein composition of synaptosomes and SVs has been best characterized by mass spectrometry. Proteomic characterization of isolated proteins or protein complexes first involves enzymatic digestion of the proteins by specific proteases. Trypsin is the most common protease used for these analyses since it cuts C-terminal to arginine and lysine residues, thereby imparting a positive charge on this end of all resulting peptides (an important characteristic that aids in MS-based sequencing). As with any organelle or subcellular fraction, synaptosomes and SV preparations will contain some level of impurity, however small. As mass spectrometers become more sensitive, these impurities are increasingly detected, even if they are at relatively low levels. Therefore, a simple 'parts list' of any protein complex (no matter how well isolated) needs to be interpreted with a degree of caution, and it is absolutely essential to conduct subsequent cell-biological validation of a given protein's role in the functioning of that protein complex before accepting it as a bona fide component.

The synaptosome preparation is used as a starting point for the isolation of several sub-synaptic fractions. These include: postsynaptic densities; terminal-specific mitochondria

and cytoplasm; presynaptic active zones; and SVs (Whittaker *et al.*, 1964). SVs can be released from synaptosomes by osmotic shock, which lyses the synaptosome membrane while leaving SV membranes largely intact. Subsequent density gradient centrifugation or glass bead column chromatography can be used to isolate a SV pool.

Proteomic and Cell Biological Analysis of Synaptosomes

The first systematic mass spectrometry characterization of synaptosome-derived material was in 2000 by the Kennedy laboratory. These studies used a one dimensional SDS PAGE gel to fractionate PSD (postsynaptic density) proteins, and analysis of individual gel bands led to the identification of 31 proteins (Walikonis *et al.*, 2000). Advances in multi-dimensional fractionation and increasingly sensitive mass spectrometers have resulted in over 2000 components now being identified from isolated PSDs (Bayes *et al.*, 2011; Trinidad *et al.*, 2005). As mentioned previously, biochemically isolated subcellular fractions will never be completely pure, and undoubtedly, a significant percentage of identified components are not truly synaptic. To begin developing a molecular level map of synaptic function, the absolute copy number per synapse of several key proteins has been determined by comparison to isotopically labeled protein standards (Cheng *et al.*, 2006).

Because the axon terminal component of synaptosomes seals up during the initial homogenization, they possess several important biological characteristics. When incubated in media containing glucose and oxygen, they maintain membrane potential, translocate metabolites and ions across their plasma membranes, and can release neurotransmitter when they are depolarized. The release of neurotransmitter upon depolarization is due to activation of voltage-gated calcium channels, which mimics the arrival of an action potential at the axon terminal. Synaptosome membranes can be depolarized by increasing the extracellular K^+ concentration, electrical stimulation, or exposure to drugs that increase the membrane permeability of Na^+ (De Bellerche and Bradford, 1972; Blaustein and Goldring, 1975).

Such an experimental paradigm has been used to profile phosphorylation of the AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor GluR1 (Munton *et al.*, 2007). Alternatively, synapses can be stimulated *in vivo* as has been done at the whole brain level using the muscarinic AChR antagonist pilocarpine (Trinidad *et al.*, 2013b). Quantitative analysis of protein dynamics at the synapse revealed the existence of a functionally associated core of synaptic proteins. This core, which included key neurotransmitter receptors as well as scaffolding proteins, displayed correlated changes in synaptic abundance in response to activity. Changes in synaptosome composition have also been characterized following chronic administration of morphine. It was demonstrated that the expression of a range of proteins were altered in response to drug exposure, most notably those regulating cell adhesion, G protein signaling, and vesicle trafficking (Abul-Husn *et al.*, 2011). Synaptosomes have been isolated from rats that had been trained to self-administer heroin. Changes in expression levels of AMPA receptors GluR2 and GluR3, as well as the NMDA (N-methyl-D-aspartate) receptor

NR2B were seen, resulting in altered AMPA/NMDA current ratio (Van den Oever *et al.*, 2008).

The protein composition of SVs and posttranslational modification states of these proteins remains an active field of investigation. To date, over 6000 proteins have been identified in synaptosome preparations (Trinidad *et al.*, 2012). Such a large number of components is perhaps not surprising given the complexity and heterologous nature of axon terminals and associated postsynaptic machinery. The mitochondria proteome alone, for example, contains over 1000 proteins (Pagliarini *et al.*, 2008). Synaptosome proteins span a wide range of functional classes. Importantly, they include a large number of posttranslational modifying proteins including kinases, methyltransferases, acetyltransferases as well as SUMO (small ubiquitin-like modifier), and ubiquitin ligases. Consistent with the central role of phosphorylation-based signal transduction, over 300 kinases have been identified in synaptosome preparations. The PTM (posttranslational modifications) content of synaptosomes has been studied at large scale for phosphorylation, O-GlcNAcylation as well as extracellular N- and O-linked glycosylation (Trinidad *et al.*, 2012, 2013a). Over 16 000 distinct sites of phosphorylation are currently known. O-GlcNAcylation is the addition of N-acetylglucosamine to serine and threonine residues on intracellular proteins. This is a dynamic and reversible modification that occurs at a relatively high frequency and the enzymes responsible for its regulation are present at the synapse (Akimoto *et al.*, 2003). To date, over 1700 sites of O-GlcNAcylation have been identified on synaptosomal proteins. This is at least an order of magnitude greater than the number of sites found in any other organ and is consistent with the high expression of OGT in the brain and at the synapse. Extracellular and transmembrane proteins are generally modified with branched N- and O-linked glycosylation (Varki and Sharon, 2009). This type of glycosylation is a challenging posttranslational modification to study because glycosylated peptides fragment extensively during tandem mass spectrometry. The resulting complex fragmentation patterns are difficult to interpret in an automated fashion. In addition, the addition of glycan structures is not template driven, as is the case for protein synthesis. Therefore, the exact sites of glycosylation, as well as nature of attached oligosaccharide cannot be determined *a priori* using genomic or bioinformatic analysis. Over 1500 unique glycopeptides are known on synaptosome proteins (Trinidad *et al.*, 2013a). Each of these instances represents a distinct glycan: glycosylation site combination.

SVs

The term 'synaptic vesicle' was first coined by De Robertis and Bennett in 1955 during a study of electron micrographs of frog sympathetic ganglia and earthworm nerve cord neuropile (De Robertis and Bennett, 1955). They observed vesicles with electron dense circumferences and relatively lighter centers that were in close spatial relationship to the presynaptic membrane. In the mammalian central nervous system, axon terminals contain approximately 10–500 SVs (Pocklington *et al.*, 2006; Schikorski and Stevens, 1997). The human brain

therefore contains an enormous number of SVs. A brain contains 10^{12} neurons, and a total of approximately 10^{15} synapses. Assuming an average of 100 SVs per synapse gives an estimate of 10^{17} SVs, a number that speaks to the centrality of SVs in transmission at chemical synapses. There are approximately 2000 neurotransmitter molecules packaged into a single vesicle giving an approximate concentration of 150 mM (Ryan *et al.*, 1993). In contrast to neurotransmitter vesicles, some aminergic neurotransmitters and neuropeptides are stored in dense core vesicles (Bauerfeind *et al.*, 1995). These vesicles are approximately 100 nm in diameter, and their trafficking and release are regulated by mechanisms that are distinct from those of SVs.

Within a couple hundred milliseconds of an action potential arriving at the axon terminal, SVs that are docked at the active zone fuse with the plasma membrane and release their neurotransmitter into the synaptic cleft (Sabatini and Regehr, 1996). SVs are docked within 100 nm of calcium channels to tightly couple calcium influx with vesicle fusion (Eggermann *et al.*, 2012). SVs at an axon terminal can be divided into three populations, which are defined based on functional differences (Alabi and Tsien, 2012). The first population is the readily releasable (i.e., docked) pool and it constitutes approximately five SVs per synapse (Dobrunz and Stevens, 1997). These vesicles are physically docked at the active zone in close proximity to voltage-gated calcium channels. The calcium-sensing proteins on these SV are thus optimally positioned to detect influx of calcium and initiate fusion. Synapses at the neuromuscular junction are of high fidelity in the sense that an incoming action potential induces fusion of multiple vesicles which results in muscle contraction with essentially 100% efficiency. In contrast, in the hippocampus the probability that an action potential will cause fusion of at least one SV is less than 30% (Murthy *et al.*, 1997). The fact that the release probability of central synapses is significantly less than 100% allows changes in a neural network to be encoded in part by increases or decreases in release probability.

The second population of vesicles is referred to as the recycling pool. This pool is not docked at the active zone, but is positioned to repopulate the readily releasable pool as those vesicles undergo fusion. The recycling pool is approximately three times larger than the readily releasable pool (Murthy and Stevens, 1999). A third pool exists consisting of vesicles which do not readily undergo fusion except during intense bouts of synaptic activity. This pool is called the resting or reserve pool and constitutes approximately 75% of all vesicles at the axon terminal (Rizzoli and Betz, 2005; Alabi and Tsien, 2012). Multiple functions for this pool of vesicles have been proposed, including a role in intracellular signal transduction, and acting to buffer the supply of soluble SV proteins during recycling so that they do not diffuse out of the synapse (Denker *et al.*, 2011). In addition, vesicles from this pool can travel between boutons, a phenomenon that may regulate synapse-specific changes in transmission efficiency (Herzog *et al.*, 2011). It is important to note that these three populations have been defined largely based on electrophysiological studies. In the case of docked vesicles, electron micrograph images clearly confirm a small subset of vesicles located proximal to the active zone, but differences between the recycling and

resting pools are not so distinct. In any case, vesicles must move between populations and at the molecular level; this likely occurs in stages rather than being a binary process.

Physical Characteristics of SVs

The average diameter of SVs varies as a function of organism and neuronal type, but it is within the range of 40–80 nm (Harris and Sultan, 1995). Within a given synaptic population, the size distribution is considerably narrower. For example, in axon terminals from the rat hippocampus the average synaptic diameter is 39 nm with a standard deviation of 5 nm (Qu *et al.*, 2009).

SVs contain numerous distinct membrane lipids. The most abundant of these are cholesterol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and sphingomyelin. The phospholipid content (which does not include cholesterol) is expected to occupy ~50% of the SV surface (Takamori *et al.*, 2006). The elucidation of most of the principle SV proteins was achieved over the course of many years using a range of techniques, chief among them being genetic analysis (for a detailed review, see Sudhof (2004)). As mentioned above, SVs can be isolated from initial synaptosome preparations (Burre and Volkandt, 2007). A number of approaches exist for their enrichment, including density gradient centrifugation, immunoprecipitation with antibodies against SV proteins, and glass bead chromatography. The resulting preparations are composed of highly purified SV, which include their luminal components (e.g., neurotransmitters) as well as any peripheral membrane proteins associated with the outer surface of the SV. Initial proteomic analysis of SV preparations revealed the identity of 72 distinct proteins (Moricano *et al.*, 2005). A study from the Jahn laboratory has become the major point of reference for understanding SV composition (Takamori *et al.*, 2006). A total of 410 proteins were found highly enriched in SVs. The absolute protein copy number per SV was determined for 15 key proteins. In addition, the average physical characteristics of the SV population were determined, including density, diameter, mass, and volume. The amount of each principle membrane lipid was measured. These factors combined to allow the development of a molecular-level model of a typical SV. Key findings of this study with respect to protein composition were that the SNARE protein synaptobrevin was present at approximately 70 copies per vesicle; neurotransmitter transporters were only present at 10 copies per vesicle; the V-ATPase that provides the proton gradient for the neurotransmitter transporters occurred at approximately 1–2 copies per vesicle. Modeling the proteins and lipids onto a vesicle architecture demonstrated that approximately 20% of the vesicle surface was occupied by transmembrane domains.

Thus far, we have a good overall understanding of a population-average SV, but much remains to be determined about the distribution and characteristics of vesicle subpopulations, both with respect to SVs at different types of chemical synapses as well as different populations of SVs within a single type of synapse. Quantitative comparisons have been performed between glutamatergic and GABAergic SVs that were isolated through the use of antibodies (Pavlos *et al.*, 2010). The vast majority of the 450 proteins identified in

this study were of similar abundance in both classes of SVs. These results indicated that the neurotransmitter transporters themselves are likely the primary determinants of specific classes of SV.

The exact roles of most SV proteins are still poorly understood. While a model exists for the protein composition of SVs, we do not yet fully understand how this set of proteins physically interacts. The binding partners of SV2, a major SV protein, have been determined (Yao *et al.*, 2010). This approach relied on creating a fusion protein of SV2 with an enrichment tag, allowing both vesicle-associated and non-vesicle-associated binding proteins to be identified. Identified binding proteins include AP-1 and AP-2 complex subunits as well as amphiphysin and EPS15. A systematic approach for sequentially enriching and identifying partners of all SV proteins will likely be needed to further our understanding of SV physiology.

Key Proteins Associated with SVs

Broadly speaking, the key proteins that participate in SV function can be organized into three categories: those involved with exocytosis, those involved with endocytosis, and those involved with neurotransmitter packaging/SV localization. While most of the proteins that regulate these functions are not fully understood, the broad outline of this picture has been worked out in detail. Below is a brief description of the most well-characterized SV-associated proteins, which is followed by a more detailed description of their interactions during different phases of the SV life cycle.

Proteins mediating exocytosis

Synaptobrevin

Synaptobrevin, along with syntaxin-1 and SNAP-25 are the three members of the SNARE complex that provide the energy to drive fusion. Synaptobrevin is an 18 kDa protein and has two principle isoforms and is localized to SVs. It is cleaved and inactivated by clostridium toxins. Inactivation of any of the three SNARE proteins prevents SV fusion.

Syntaxin-1

Syntaxins are a family of membrane proteins primarily localized to the plasma membrane of the presynaptic active zone, of which syntaxin-1 is the primary form involved in vesicle fusion. In addition to participating in the SNARE complex, syntaxins bind synaptotagmin on SVs in response to calcium entry. While syntaxin's fusion-related activity depends on its localization in the plasma membrane, some percentage of syntaxin is present in SVs. This is likely due to syntaxin being associated with synaptobrevin when the latter is endocytosed into recycling SVs. It is cleaved and inactivated by botulinum toxin.

SNAP-25

SNAP-25 is a membrane-associated protein of the active zone. It binds to membranes via palmitoylation of multiple cysteine side chains. Like syntaxin, SNAP-25 can interact with synaptotagmin in a calcium dependent fashion. Two splice variants of SNAP-25 exist that vary in their developmental and tissue

distribution (Nagy *et al.*, 2005). It is present in SVs, likely in a similar fashion to syntaxins. Like syntaxin, SNAP-25 is cleaved by botulinum toxin, rendering it inactive.

Synaptotagmin

Synaptotagmins are a family of proteins, of which synaptotagmin-1 has a primary role in SVs. It is a single-pass transmembrane protein containing two cytosolic C-terminal C2 domains that bind calcium. Upon calcium binding, synaptotagmin binds to the SNARE complex and displaces complexin, thereby allowing SV fusion with the plasma membrane (Maximov *et al.*, 2009).

SV2

Synaptic vesicle glycoprotein 2 (SV2) occurs in two main isoforms in the brain, SV2A and SV2B. This protein can bind two adenine molecules and possibly links cellular energy state to vesicle release. Mice engineered to lack both SV2 isoforms possess a smaller number of readily releasable SVs, which implicates SV2 in vesicle priming events (Yao and Bajjalieh, 2008).

Rab3A

The Rab family of proteins contains over 70 proteins in humans and members of this family are monomeric G proteins of the Ras superfamily. Rabs are peripheral membrane proteins that function in essentially all membrane trafficking events in the cell. Rabs bind GDP/GTP and are active in their GTP-bound form and inactive when bound to GDP. Specific Rabs are localized to different membrane compartments. Rab3A is present on SVs, and in its active form it is involved in tethering vesicles to the active zone (Geppert *et al.*, 1997).

Proteins mediating endocytosis and vesicle recycling

NSF

NSF is an acronym for *N*-ethylmaleimide-sensitive factor, an AAA ATPase that exists as a homohexamer of NSF monomers (Glick and Rothman, 1987). NSF acts by coupling the energy of ATP hydrolysis to drive dissociation of SNARE complexes that are present in the *cis* conformation on the plasma membrane. These versions of the SNARE complex exist together in the plasma membrane after vesicle fusion. In order for synaptobrevin to be endocytosed and repackaged into SVs, it must be first separated from SNAP-25 and syntaxin-1 via the action of NSF.

Clathrin

Clathrin-mediated endocytosis is the primary mechanism for SV recycling at the synapse (Pearse, 1976). Two versions of clathrin light chain and two versions of clathrin heavy chain exist. Functional clathrin exists as a heterohexamer of three clathrin heavy chains and three light chains organized in a triskelion arrangement. As membrane is endocytosed from the plasma membrane to reconstitute a SV, clathrin polymerizes into a rounded lattice network to promote endocytosis.

Clathrin adaptor proteins

Clathrin by itself does not polymerize directly onto endocytosing membranes. Rather a family of adaptor proteins directly binds the membrane and mediates clathrin recruitment,

ultimately forming a layer between the clathrin lattice and the membrane. Examples of adaptor proteins include the AP2 complex, AP180, and epsin (Zhang *et al.*, 1998; Shih *et al.*, 1995).

Cysteine-string protein

Cysteine-string protein (CSP) interacts with both syntaxin-1 and synaptotagmin. It likely acts as a chaperone to mediate refolding of denatured SNARE proteins prior or subsequent to endocytosis (Fernandez-Chacon *et al.*, 2004).

Proteins regulating neurotransmitter packaging and SV localization

V-ATPase

The vacuolar ATPase acidifies the lumen of SVs by using the energy of ATP hydrolysis to pump protons into SVs. The ATPase consists of a V1 multiprotein complex that hydrolyzes ATP and a V0 complex that is responsible for translocating protons.

Neurotransmitter transporters

The exact transporter proteins present on an SV vary as a function of synapse type. In general, neurotransmitter transporters will be present not only on SVs, but also in the pre-synaptic plasma membrane as well as neighboring glial cells. The latter two are involved in reuptake of neurotransmitter and termination of synaptic signaling. SV neurotransmitters represent distinct proteins from their plasma membrane counterparts. Unique vesicle transporters exist for glutamate, GABA, glycine, monoamines, and adenosine. A given neurotransmitter may have more than one protein capable of mediating its transport. For example, there are three distinct glutamate transporters (VGLUT1-3).

Synapsin

Synapsins are a family of proteins with three genes in humans. These proteins play a role in localization of SVs, thereby controlling the number of vesicles that are at the active zone and ready for fusion. Synapsins link SVs to the cytoskeleton. The exact mechanism of regulation by synapsin remains unclear, but it is likely that depolarization of the nerve terminal activates the kinase PKA which phosphorylates synapsin. This phosphorylation event weakens the binding of synapsin to the cytoskeleton, thereby mobilizing SVs and allowing them to move to the active zone to replace recently fused vesicles (Bahler and Greengard, 1987).

Synaptophysin

Synaptophysin is highly abundant in SVs, and at 31 copies per vesicle is second only to synaptobrevin in molar amount. Despite its relative abundance, little is known about its biology. It can physically associate with synaptobrevin; however, it is not absolutely required for SV function. Mutant mice deficient in synaptophysin are largely normal (Eshkind and Leube, 1995) but display minor alterations in behavior (Schmitt *et al.*, 2009).

The Synaptic Vesicle Life Cycle

Different neuronal systems have been used to study SVs (Rizzoli and Betz, 2005). These include the calyx of Held and hippocampal nerve termini from rodents, motor nerve terminals of both *Drosophila* and frog, and the ribbon synapse from goldfish. Each of these systems has its relative experimental advantage such as large size (making it amenable to electrophysiological measurement), or ease of genetic manipulation (which allows individual components to be selectively reduced or eliminated). The assumption (generally found to be true) that comes with using a diverse array of biological systems is that the results obtained in a given system will be broadly applicable to most types of synapses.

The notion of SV recycling was first proposed by Heuser and Reese (1973) to describe the discrete stages in the life cycle of SVs. This stemmed from the observation that a mechanism must exist to regenerate SVs that have released their neurotransmitter contents and fused with the plasma membrane. More broadly, the steps below outline the basic stages that occur as vesicles are formed from the Golgi, migrate to axon terminals, dock with the active zone, then fuse with the plasma membrane, and are ultimately endocytosed and reloaded with neurotransmitter.

Formation in the ER/Golgi and trafficking to the synapse

Membrane components of SVs transit through the Golgi apparatus and cluster into domains. These domains subsequently bud off as vesicles. It is not known if these vesicles contain the full complement of SV proteins (and can therefore be considered 'mature') or if additional sorting/processing occurs upon arrival at axon terminals. The vesicles that bud from the Golgi are directed toward axons and vary in their size and shape (Tsukita and Ishikawa, 1980). However, a subpopulation of these vesicles does possess diameters consistent with SVs (Yonekawa *et al.*, 1998). Vesicles destined for axon terminals are transported in an anterograde fashion along axons using the motor protein kinesin (Okada *et al.*, 1995), although distinct populations of vesicle/motor complexes exist (Kaether *et al.*, 2000).

Loading with neurotransmitter

SVs contain transporters for their respective neurotransmitters. As a class, these pumps are anti-transporters and couple efflux of protons with influx of neurotransmitter. In the case of glutamate, GABA, and glycine, two protons are pumped out of the vesicle lumen for every molecule of neurotransmitter pumped in. In the case of catecholamine, histamine, serotonin, and acetylcholine, one proton is expelled for every neurotransmitter pumped into the vesicle. The proton gradient is supplied by the vacuolar ATPase complex, which uses the energy of ATP hydrolysis to pump protons across membranes (in this case from the cytosol into the vesicle lumen). It is estimated that 10 copies of a given neurotransmitter receptor are present on average per SV (Takamori *et al.*, 2006). There are approximately 2000 glutamate molecules per vesicle (Ryan *et al.*, 1993). Measurements in slice cultures give an estimate of 8.4 molecules s^{-1} pumped into a vesicle per neurotransmitter transporter (Hori and Takahashi, 2012).

Docking at the active zone and priming the fusion machinery

The bacteria *Clostridium botulinum* and *Clostridium tetani* secrete botulinum and tetanus toxin, respectively. These toxins were important to the initial elucidation of the SV fusion machinery. They act as proteases and cleave components of the SNARE complex, which inhibits vesicle fusion. This provided a handle to determine the identity of the SNARE proteins (Link *et al.*, 1992).

Vesicles dock at the active zone via interactions between proteins of the SNARE complex, namely synaptobrevin, SNAP-25, and syntaxin. The term 'SNARE' is derived from 'SNAP receptor.' SNAP in turn is an acronym for 'soluble NSF attachment protein.' Synaptobrevin (also known as VAMP) is a single-pass transmembrane protein located on SVs and anchored to the vesicles via its C-terminus. Syntaxin and SNAP-25 are localized to the plasma membrane via their C-terminus and palmitoylation of cysteine residue side chains, respectively. These proteins interact via a parallel four-helix bundle (Poirier *et al.*, 1998). Syntaxin and synaptobrevin each possess a single SNARE motif domain and consequently each contributes a single helix to the bundle. SNAP-25, in contrast, contains two SNARE motif domains, and contributes two helices to the binding complex (Sutton *et al.*, 1998).

While vesicles are docked at the active zone, partially assembled SNARE complexes also interact with SM proteins (for 'Sec1/Munc-18-like'), most notably Munc-18 and Munc13. While this interaction is required for SV fusion, the exact roles played by SM proteins remain unclear. Munc-18 is able to bind to an SM interaction motif on the N-terminus of syntaxin, which allows it to interact with a fully assembled SNARE complex. However, Munc-18 is also able to interact with a second site on syntaxin, primarily while syntaxin is in a closed formation and unable to interact with synaptobrevin and SNAP-25 to form the SNARE complex (Dulubova *et al.*, 1999). Overall, the interactions between Munc18 and syntaxin likely regulate the ability of syntaxin to interact with other SNARE proteins as well as any additional binding partners (Burkhardt *et al.*, 2008). The crystal structure of Mun domain of Munc18 has been solved and is shown to belong to the same structural family as other tethering factors such as the exocyst complex subunit Sec6p (Li *et al.*, 2011).

Fusion with the plasma membrane and release of neurotransmitter

Incoming action potentials depolarize axon terminals, which results in an influx of calcium via voltage-gated calcium channels. This leads to an overall increase in intracellular calcium, but more important than the overall concentration of calcium in the axon terminal is the local concentration of calcium in the active zone. SVs contain a calcium sensor, which is a single-pass transmembrane protein named synaptotagmin. Synaptotagmin possesses two C2 domains that bind calcium and are involved in regulation of SV fusion. Upon calcium binding, synaptotagmin-1 is able to bind simultaneously both SV membrane and plasma membrane (Arac *et al.*, 2006). This brings the SV and plasma membrane domains in closer proximity, promoting fusion.

When vesicles are docked at the plasma membrane, synaptobrevin, SNAP-25, and syntaxin interact in 'trans' fashion, with synaptobrevin in the SV membrane and SNAP-25

and syntaxin in the plasma membrane. Upon exocytosis, the vesicles fuse with the plasma membrane, and all three SNARE components remain associated. At this stage, the complex is then located entirely in the plasma membrane in a 'cis' conformation. The X-ray crystal structure of the SNARE complex composed of syntaxin 1A, SNAP-25, and synaptobrevin 2 has been determined. The complex assumes a helical bundle configuration with extensive interactions of amino acid residue side chains (Stein *et al.*, 2009).

Synapsin is a regulatory protein that is involved in calibrating the number of SVs that are able to undergo fusion at any given time. In its dephosphorylated state, it has been shown to tether SVs to the cytomatrix, thereby organizing the reserve pool of vesicles. Depolarization of the axon terminal activates a number of kinases that can phosphorylate synapsin, including CaMKII, PKA, and MAPK. Upon phosphorylation, synapsin dissociates from SVs (Greengard *et al.*, 1993). This dissociation promotes the migration of SVs from the reserve/recycling to readily releasable pool (Bloom *et al.*, 2003).

As little as two or three SNARE complexes may be needed to enable vesicle fusion (Mohrmann *et al.*, 2010). This applies mainly to fast-type SV fusion events and raises the possibility that variation in the number of SNARE complexes per vesicle may explain the range in vesicle release probabilities. With approximately 70 copies of synaptobrevin per SV, it is possible that vesicles can be docked to the active zone with a fairly broad range in their number of SNARE complexes. However spatial constraints make it unlikely that more than a small portion of these synaptobrevin molecules can simultaneously be involved in SNARE complexes at any given time. Continuous pulling by the SNARE complex is required throughout the exocytosis process, as has been demonstrated from mutagenesis studies on synaptobrevin (Kesavan *et al.*, 2007). Increasing the length of the juxtamembrane region on synaptobrevin decreases overall fusion efficacy.

Endocytosis and reformation of a fusion-competent synaptic vesicle

SV fusion is an exothermic process, and upon complete vesicle fusion, the three SNARE proteins convert from a *trans* to a *cis* conformation. NSF then acts as an ATPase and uses the energy of ATP hydrolysis to disassemble this trimeric complex, thereby releasing them into a higher-energy unbound state to be used again in subsequent rounds of exocytosis. Synaptobrevin is then repackaged into SVs, leaving the majority of syntaxin 1 and SNAP-25 on the plasma membrane.

Three related mechanisms have been proposed to account for the reconstitution of SVs after exocytosis. These mechanisms are 'kiss and run,' clathrin-mediated endocytosis, and bulk endocytosis (Figure 1). Experimental evidence exists to support all three models and the relative degree to which each occurs seems in large part a function of the synapse type studied and how vigorously the axon terminals are stimulated. That being said, clathrin-mediated endocytosis appears to account for the majority of SV recycling under most levels of activity.

Kiss and run fusion

The term kiss-and-run fusion was coined by Ceccarelli (Ceccarelli *et al.*, 1973) and refers to the notion that during some exocytosis events, SVs do not fully fuse with the plasma

Figure 1 Two models of synaptic vesicle fusion and subsequent endocytosis. Shown in both figures are synapses consisting of an axon terminal (top) and its corresponding postsynaptic spine (bottom). Three populations of SVs are present in the axon terminal. The readily releasable docked pool is tethered to the plasma membrane at the active zone. Upon fusion, neurotransmitter is released into the cleft between the axon terminal and spine. Neurotransmitter diffuses across the cleft and is bound by ligand gated ion channels (neurotransmitter receptors) on the postsynaptic surface. The recycling pool of vesicles is positioned to replenish the docked pool as the latter is depleted by synaptic activity. The resting pool of vesicles does not generally exocytose directly, except perhaps during prolonged intense bouts of activity. (a) The ‘kiss and run’ model of vesicle recycling. The SVs in the active zone show the sequence of events during vesicle fusion. A small, transient pore opens between the SV and the plasma membrane. This allows most of the neurotransmitter to be released. The fusion pore then seals up, reconstituting a mature SV which then is refilled with neurotransmitter and becomes localized to the recycling pool. (b) The clathrin-mediated endocytosis model of vesicle recycling. In this model, SVs collapse completely or almost completely into the plasma membrane, largely mixing their protein and lipid contents and releasing all of their neurotransmitter. Endocytosis occurs proximal to the active zone. Endocytosing vesicles are coated in adaptor proteins and clathrin. Upon fission from the plasma membrane, the clathrin un-coats and vesicles either fill directly with neurotransmitter or may traffic first to an endosomal compartment for further protein sorting.

membrane (**Figure 1(a)**). Rather they form a small fusion pore between the SV and the plasma membrane, which allows neurotransmitter to diffuse through while retaining the overall spherical shape of the SV. This fusion pore is transient, and upon closure, an essentially intact SV is reformed, lacking only in luminal neurotransmitter. Such a mechanism provides a straightforward way to reconstitute SVs. However, from an energetic perspective, there is a strong drive on the part of curved membranes to flatten out subsequent to any initial pore formation, which would imply that the vesicles quickly collapse almost completely into the plasma membrane upon triggering of fusion. Therefore, a mechanism must exist to restrain this from happening, perhaps in the form of a molecular collar around the neck of the fusion pore.

Clathrin-mediated endocytosis

Clathrin-mediated endocytosis is a complex mechanism involving approximately 20 proteins. For a detailed review of the process, see [Saheki and De Camilli \(2012\)](#). It is believed to be the primary mechanism by which vesicles are retrieved after complete fusion with the plasma membrane. Clathrin-mediated endocytosis occurs after complete fusion of SVs to the plasma membrane (**Figure 1(b)**). Clathrin adaptor proteins mediate association between phospholipids and proteins on the plasma membrane and the associating clathrin coat that encloses the endocytosing vesicle. Major adaptor proteins include the AP2 complex, AP180, epsin and stonin. These adaptors are able to associate with each other as well as molecules of synaptotagmin, SV2, and synaptobrevin that are present on the plasma membrane after fusion ([Haucke and](#)

[De Camilli, 1999](#); [Nonet et al., 1999](#)). These multiple cross-linking interactions likely nucleate endocytosis. Multiple copies of the clathrin triskelion are then recruited to the adaptor proteins where they polymerize into a spherical lattice. This results in a mostly formed clathrin-coated vesicle that is attached by a thin stalk to the plasma membrane. Final fission of the vesicle is achieved by the action of a GTPase known as dynamin ([Koenig and Ikeda, 1989](#)). Quickly after vesicle fission, the clathrin coat depolymerizes via the action of hsc70 ([DeLuca-Flaherty et al., 1990](#); [Guan et al., 2010](#)). This process can generate a functional SV directly without the need for fusion of the clathrin-coated vesicle with an endosomal compartment ([Takei et al., 1996](#)).

Bulk endocytosis

Bulk membrane endocytosis has been observed to occur, generally after strong synaptic stimulation or under conditions where clathrin-mediated endocytosis is inhibited. Relatively large invaginations of the plasma membrane can be seen by electron microscopy. These infoldings break off from the plasma membrane and generate endosome-like vacuoles ([Miller and Heuser, 1984](#)). These vacuoles are not stable and presumably undergo fission events concurrent with the formation of new SVs ([Teng et al., 2007](#)).

Extracellular Vesicles

Vesicles are small organelles consisting of fluid enclosed by a lipid bilayer. Their importance in intracellular transport and compartmentalization of the intracellular milieu has been appreciated with the 2013 Nobel Prize in Physiology or Medicine for Rothman, Schekman, and Südhof for their discoveries of machinery regulating vesicle traffic. Besides vesicular traffic inside cells, it is already known for several decades that cells also release vesicles into their environment. Nowadays, it has become clear that all living cells ranging from unicellular bacteria, archaea, and fungi to cells from parasites, plants, and animals have the capacity to release vesicles into the extracellular milieu. Vesicle release thus spans all kingdoms of life and is an evolutionary conserved process impacting organisms throughout the tree of life. The overall presence of extracellular vesicles (EVs) in all body fluids and the environment (e.g., EVs are abundantly present in oceans), further corroborates that these extracellular organelles are part of ecosystems.

The population of EVs is very heterogeneous and although cells constitutively release EVs, the amount of EVs and their cargo of bioactive macromolecules such as proteins, lipids, and nucleic acids are highly regulated and dependent on the cell type and cellular state. Interestingly, the composition of EVs is markedly different from the cell of origin. EVs from eukaryotic cells are enriched in specific lipids (e.g., cholesterol, sphingomyelin, and ceramide) and in specific proteins that are involved in the endosomal route and vesicle formation (e.g., tetraspanins, members of the Rab GTPase family and chaperones) (Kowal *et al.*, 2014). Also, the glycosylation pattern of EVs is distinct from the cell of origin. Nowadays, it is clear that besides selected sets of proteins and lipids, EVs also contain a wide variety of nucleic acids including all kinds of noncoding RNA biotypes, transposable elements, and extrachromosomal DNA (Villarroya-Beltri *et al.*, 2014). The demonstration that EV-associated RNAs were functionally transferred to recipient cells (Ratajczak *et al.*, 2006; Valadi *et al.*, 2007) further substantiated the concept that EVs are vehicles for intercellular communication involved in the horizontal transfer of combined biological signals to specific target cells.

EV-mediated intercellular communication has several advantages. The regulated release and composition of EVs allows that tailor-made nanoparticles composed of different physiologically relevant signal molecules are spread in a timely fashion. The incorporation into EVs protects luminal cargo for degradation and prevents undesired collateral effects. The presence of specific receptors on the surface contributes to specific targeting to destine cells. Finally, the processing of EVs after binding to the target cell determines how EV-associated components can signal to the target cell.

The Physiological Role of EVs: From Waste Bin to Versatile Transporter of Biological Signals

Although the process of microvesiculation is known for several decades, the physiological relevance of EVs is just emerging. Already in the 1960s, both prokaryotic cell-derived EVs from Gram-negative bacteria and eukaryotic cell-derived EVs from platelets (platelet dust) and bone matrix were identified. In historical perspective, the first EVs with a defined physiological function were bone matrix EVs having a role in bone mineralization and bone homeostasis (Golub, 2009) and procoagulant platelet-derived EVs in hemostasis (Owens and Mackman, 2011). In the 1980s, it was observed that during reticulocyte maturation, organelles filled with small membrane-enclosed vesicles (30–100 nm in size) were present in the cytosol which could fuse with the plasma membrane thereby releasing their intraluminal vesicles in the extracellular milieu (Harding *et al.*, 1983; Pan *et al.*, 1985). These so-called exosomes were regarded as waste bins dumping obsolete cellular products in the environment. The recent observations that EVs may be involved in the outsourcing of autophagy to other cells suggest that EVs play an active role in the recycling of cellular components. The findings in the 1990s that EVs derived from B lymphocytes and dendritic cells can activate adaptive immune responses were indicative for a physiological role of EVs in the immune system (Raposo *et al.*, 1996; Zitvogel *et al.*, 1998). Nowadays the picture emerges that EVs are an integral part of the innate and adaptive immune system involved in immune regulation (Robbins and Morelli, 2014). In mammals, EVs have additionally been shown to be involved in many physiological processes including embryonic development and homeostasis (Zhang and Wrana, 2014), reproduction and pregnancy (Ronquist, 2012; Arck and Hecher, 2013), communication in the nervous system (Frühbeis *et al.*, 2013), and tissue repair (Tetta *et al.*, 2011).

For unicellular organisms intercellular communication is essential to control population density and differentiation. In bacteria this so-called quorum sensing is a highly regulated process in which bacterial EVs play a role in the exchange of essential information between bacteria (Kulp and Kuehn, 2010; Deatherage and Cookson, 2012). Furthermore, bacterial EVs can interact with other bacterial species which can result in either negative effects, for example, lysis of bacteria, or positive effects such as the transfer of antibiotic-resistance enzymes or the transfer of enzymes for the acquisition of nutrients (Kulp and Kuehn, 2010; Deatherage and Cookson, 2012). Bacterial EVs are also involved in biofilm formation and as such play a general role in optimal niche formation. Under stress-conditions hypervesiculation has been observed in bacteria and it is assumed that EVs play a role in the defense mechanism to cope with harsh conditions (Kulp and Kuehn, 2010; Deatherage and Cookson, 2012). The findings that bacterial

EVs are very abundant in natural ecosystems, such as oceans, and that these EVs support the growth of heterotrophic bacterial cultures in these natural systems further substantiates the physiological role of bacterial EVs in natural ecosystems (Biller *et al.*, 2014).

Also parasites use quorum-sensing-like mechanisms in which EVs mediate the transmission of signals between parasites (Twu and Johnson, 2014). Parasite-derived molecules can be found on EVs derived from the parasite itself or, in case of intracellular parasites, on EVs derived from infected host cells. For example, malaria parasites inside red blood cells use EVs released by infected cells as vehicle to signal and sense malaria parasites present in other erythrocytes, thereby promoting a collective differentiation to sexual forms of the parasite population (Regev-Rudzki *et al.*, 2013). This communication and sensing mechanism are probably widespread among protozoa, as these populations often shift in a synchronized fashion from one state to another, reminiscent of quorum-sensing in bacteria. A recent finding in fruit flies indicates that EVs produced by cells of the accessory glands in the male reproductive tract can reprogram female behavior, thereby inducing reproductive advantage of the first male to mate (Corrigan *et al.*, 2014). These findings clearly demonstrate that EV-mediated regulation of intercellular communication reaches far beyond the confinements of the cell of origin and even of the organism in which the EVs are produced.

EVs in Cross-Kingdom Communication

In experimental science many studies are performed using isolated cells and different organisms are usually studied separately. In nature, however, different organisms continuously compete and collaborate in complex ecosystems. The fact that EV production is such an evolutionary conserved process, together with the abundance of EVs present in body fluids and the environment, triggered the idea that EVs play a role in cross-kingdom communication and even in the communication between the three domains of life: Eukaryota, and the prokaryotic Bacteria and Archaea (Figure 1).

Indeed it becomes apparent that prokaryotic cell-derived EVs not only play a role in the communication between prokaryotes but also between prokaryotes and their eukaryotic host. During host–pathogen interactions, pathogenic bacteria release EVs impacting pathogen survival and antibiotic resistance. These versatile EVs highly enriched in virulence factors are delivered intracellularly, for example, inside phagosomes, or extracellularly to host cells resulting in either immune activation or immune evasion. For example, bacterial EVs containing Toll-like receptor (TLR) and nucleotide-binding oligomerization domain receptor (NLR) activation ligands have been implicated in innate immune activation and induction of inflammation (Ferrand and Ferrero, 2013). Besides pathogenic effects, bacterial EVs can also contribute to

Figure 1 EV-mediated communication is an evolutionary conserved mechanism of intercellular communication. (1) In multicellular organisms EVs can signal to neighboring cells as well as to distant cells via body fluids or in plants via the phloem. (2) In unicellular organisms or intracellular living parasites, EV-mediated signal transmission plays a role in controlling population density and differentiation, i.e., quorum sensing. (3) Between different prokaryotes, EV-mediated communication plays a role in niche formation, competition, and symbiosis. (4) EV-mediated cross-kingdom communication between prokaryotes and eukaryotes, and (5) between different eukaryotic kingdoms is involved in pathogenicity and immune modulation. EVs are derived from blood cells and vessels.

symbiosis between bacteria and the host. For example, EVs from human commensal bacteria can communicate with immune cells of the host and induce immune tolerance (Shen *et al.*, 2012). Now there is clear evidence that prokaryotic cell-derived EVs can influence eukaryotic organisms in both the plant and mammalian world. The reciprocal interaction, influencing prokaryotes via eukaryotic cell-derived EVs, needs to be further substantiated. Yet, there is some evidence for this EV-pathway in higher plants. In higher plants, pathogens and microbiota typically do not enter the host cells. Hence the molecular interaction between these organisms and the host occur in the extracellular space, the apoplast. During environmental stress, such as pathogen attack by bacteria or fungi, the plant defense system releases specific proteins in the apoplast (Regente *et al.*, 2012; Kaffarnik *et al.*, 2009). Secretome analysis and direct evidence for fusion of multivesicular bodies (MVBs) with the plasma membrane resulting in the release of EVs indicate that plant-derived EVs participate in the defense response to pathogens (Delaunois *et al.*, 2014). Although no direct evidence is available on mammalian cell-derived EVs influencing prokaryotic cells, evidence exists for the cross talk with eukaryotic parasites. During protozoan parasite infections, gastrointestinal epithelial cell-derived EVs from the host containing antimicrobial peptides, can be released in the gut lumen and as such can be regarded as an arm of the mucosal immunity relevant to antimicrobial defense (Hu *et al.*, 2013). Also eukaryotic parasites release EVs, either intracellularly for intracellular living parasite stages or extracellularly for free-living stages. These EVs can promote growth and increase virulence of the parasites or can modulate the host immune response (Mantel and Marti, 2014). Also fungal EVs can interfere with the activity of host immune effector cells and can increase fungal pathogenesis (Rodrigues *et al.*, 2014). The observation that specific rice-derived microRNAs could be detected in blood after rice consumption and can regulate mammalian gene expression (Zhang *et al.*, 2012) has sparked the idea that diet-derived EVs can modulate host cells. Although it is still a matter of debate whether diet-derived microRNAs are associated with EVs and whether their amount in the host reaches high enough levels to be of any physiological relevance (Witwer *et al.*, 2013b), the idea that cross-kingdom communication is possible via EVs derived from plant-food components is intriguing and may represent another level of communication between different organisms.

Future studies addressing EV-mediated communication between prokaryotes and parasites or fungi, as well as between animals and plants, may uncover additional EV pathways between these biological systems (Figure 1). Altogether, the picture emerges that nano-sized EVs are master regulators in and between biological systems. Having the cells as confined building blocks for individual organisms, the sensing and signaling via EVs adds an extra level of regulation in biological systems.

EV Biogenesis

The ultimate physiological effect of EVs is dependent on their cargo. EVs contain functional proteins, lipids, and nucleic acids that are incorporated in EVs in a highly regulated

manner. The EV cargo is dependent on the cell of origin and the state of this cell. Additionally, the intracellular origin may determine the composition of EVs. Eukaryotic cells can release a plethora of different kinds of EVs that can be classified based on size and biogenesis route (Figure 2).

During programmed cell death, apoptotic cells release the so-called apoptotic bodies, which are relatively large (Raposo and Stoorvogel, 2013). Cancer cells can also release relatively large EVs; oncosomes (Morello *et al.*, 2013). However, the vast majority of EVs released by living cells are much smaller in size (<200 nm). These EVs can be formed either by budding of the plasma membrane, often referred to as microvesicles, microparticles, or ectosomes, or can be derived from MVBs, the so-called exosomes (Kowal *et al.*, 2014). Although the biogenesis, and thus cargo and function, may be diverse for small EVs (<200 nm) no discriminatory markers are available yet to distinguish plasma membrane-derived EVs from exosomes.

The EV biogenesis pathways, in particular the exosome pathway, are best studied in mammalian cells. Although originally thought that EVs always bud from the plasma membrane, studies on reticulocyte maturation in the 1980s described a more complex mode of EV release; the exosome pathway (Harding *et al.*, 1983; Pan *et al.*, 1985). Later, this pathway has been confirmed to exist in many eukaryotic cells. Exosomes are derived from the endosomal pathway in which intraluminal vesicles are formed by inward budding inside endosomes. Instead of degradation into lysosomes, the resulting MVBs fuse with the plasma membrane thereby releasing the intraluminal vesicles, exosomes, in the extracellular milieu. Different families of molecules are involved in intracellular vesicle formation and the subsequent release of exosomes, suggesting that even exosomes can be further divided in subtypes (Kowal *et al.*, 2014). In eukaryotic cells the endosomal sorting complex required for transport (ESCRT) machinery is involved in the formation of intraluminal vesicles and regulates membrane budding processes at the cell surface. ESCRT complexes (ESCRT 0-III) play a role in ubiquitin-dependent cargo selection and clustering, bud formation and vesicle scission. The involvement of the ESCRT machinery in exosome biogenesis is corroborated by the general identification of ESCRT components TSG101 and Alix in EV proteomics studies (Kowal *et al.*, 2014). An alternative ESCRT-independent pathway for the biogenesis of intraluminal vesicles appeared to be mediated by a lipid-dependent (ceramide-dependent) mechanism. The lipid composition of exosomes shares many properties with lipid rafts, for example, the enrichment in cholesterol, sphingolipids, and ceramides. Ceramides cluster in microdomains and favor budding processes (Raposo and Stoorvogel, 2013). Whether multiple mechanisms of intraluminal vesicle biogenesis occur in a single MVB or whether different mechanisms occur in different MVB types within an individual cell needs to be validated. For the specific sorting of proteins into exosomes also tetraspanins, four transmembrane domain family proteins, and chaperone HSC70 are involved. Although the packaging of nucleic acids in EVs has not yet been fully resolved, the finding that sumoylated protein hnRNP2B1 controls the selection of microRNAs through the recognition of sequence motifs indicates that incorporation of nucleic acids in EVs is a selective process (Villarroya-Beltri *et al.*, 2013). The subsequent

Figure 2 Heterogeneity of mammalian cell-derived EVs. Cells undergoing apoptosis release large EVs, apoptotic bodies. Also living cancer cells can produce EVs in a similar size range as apoptotic bodies. However, the majority of living cells produces much smaller EVs. In the size range of <200 nm it is difficult to discriminate between plasma membrane-derived EVs and EVs derived from the endosomal system, i.e., exosomes, because of the lack of unique markers to discriminate between these EV subsets.

mobilization of MVBs to and fusion with the plasma membrane is controlled by the RAB family of small GTPase proteins. For the release of exosomes RAB27A, RAB11, and RAB35 have been implicated (Kowal *et al.*, 2014). Little is known about the machinery that finally drives MVB fusion with the plasma membrane or direct EV budding from the plasma membrane, although increasing intracellular Ca^{2+} concentrations seem to be a central trigger (Raposo and Stoorvogel, 2013). Also for EVs budding from the plasma membrane, phospholipids and proteins form microdomains at the plasma membrane similar to lipid rafts. Budding of these plasma membrane microdomains, containing associated protein/RNA packages, requires local disassembly of the cytoskeleton. Translocation of phosphatidyl-serine to the outer leaflet can trigger this membrane budding and subsequent EV formation. In the formation of plasma membrane-derived EVs specific factors such as ARF-6 (GTP-binding protein ADP-ribosylation factor 6) interacting with cytoskeletal structures, TSG101, and the VPS4 ATPase are proposed to play a role (Raposo and Stoorvogel, 2013).

Although the formation of EVs by Gram-negative bacteria is already known for almost 50 years, vesiculation in bacteria is not well understood. EVs from Gram-negative bacteria are

spherical lipid bilayer-enclosed vesicles ranging in size from ~20 to 300 nm. Because these EVs consist mainly of typical outer membrane components of Gram-negative bacteria, for example, lipopolysaccharide (LPS), it is assumed that these EVs pinch off from the outer membrane and hence are often called outer membrane vesicles (OMVs). Since also cytoplasm-derived proteins consistently end up in these vesicles and certain proteins are enriched or excluded in these EVs, an active sorting mechanism during OMV biogenesis has been suggested (Kulp and Kuehn, 2010). Aside from lipids and proteins, RNA and DNA are also associated with bacterial EVs. There is growing evidence that also Gram-positive bacteria and *Archaea* produce EVs but their biogenesis is still obscure. Based on the differences in cell wall architecture between Gram-negative and Gram-positive bacteria it is unlikely that the biogenesis pathways of EVs are comparable (Deatherage and Cookson, 2012). Although taxonomically distant, EV release by fungi, parasites, and *Archaea* share some basic features and the EV biogenesis in *Archaea* shares similarities with both prokaryotic and eukaryotic mechanisms, for example, the involvement of ESCRT-III and VPS4 homologs (Deatherage and Cookson, 2012). Eukaryotic microbes, including fungi and parasites, can release EVs by direct budding from the cell

surface, as well as from the MVB route. These EVs contain microbial components (proteins, lipids, and nucleic acids) and many associated proteins lack the classical secretory signal sequences. However, many aspects of EV biogenesis of intracellular parasites are still elusive. For example, the biogenesis of EVs in malaria parasite-infected red blood cells which lack internal membranes and the machinery for exocytosis and endocytosis. Analysis of EVs released by infected red blood cells indicated that these EVs are enriched for host ARF-6 and VPS4 proteins, suggesting host machinery involved in EV biogenesis. Furthermore, these EVs contain parasite proteins derived from Maurer's Clefts structures; parasite-induced membrane platforms anchored to the host cell cytoskeleton involved in protein trafficking from the parasite to the red blood cell surface (Mantel and Marti, 2014). Also *Leishmania* parasite-infected macrophages release EVs with mammalian exosomal proteins, as well as *Leishmania* orthologues to ESCRT-III components. It is currently not clear how this parasite triggers EV formation, and how these EVs cross the phagolysosome and are eventually secreted in the environment (Mantel and Marti, 2014). EVs derived from the extracellular parasite *Trichomonas vaginalis* also show a high similarity with mammalian EVs including components of the ESCRT machinery, tetraspanin homologs and small RNA species of as yet unknown function (Mantel and Marti, 2014). The presence of EV-associated ESCRT components in different eukaryotic lineages and in *Archaea* supports the idea that EVs are an ancient mechanism for intercellular communication. The plasma membrane is in general the final barrier for EV release. Fungal and plant cells, however, are surrounded by a complex and dynamic cell wall which needs to be crossed before EVs are released in the environment. Despite this barrier, EVs have been isolated from culture supernatants indicating that transport across the cell wall occurs in fungi and plants (Rodrigues *et al.*, 2014; Regente *et al.*, 2012). The knowledge on the biogenesis of fungal and plant-derived EVs destined for release into the environment is still in its infancy. In fungal EVs, glycolipid components of the fungal cell wall are identified and many EV-associated proteins lack the characteristic signal peptide required for conventional protein secretion (Rodrigues *et al.*, 2014). Also in apoplast fractions, for example, the extracellular compartment of plant cells, EVs have been identified that contain leaderless proteins, as well as a homolog (68% identity) of the human Rab11a GTPase (Regente *et al.*, 2012).

EVs in Disease

Besides a role in normal physiology, EVs are also involved in many pathological processes. During bacterial and parasite infections, comprising both helminths and parasitic protozoa, pathogen-derived EVs are released and can influence host cells in many different ways to evade host defense mechanisms and to establish and propagate infection (Marcilla *et al.*, 2012; Twu and Johnson, 2014). Invasive intracellular pathogens (e.g., *Mycobacteria*, *Leishmania* sp., and *Plasmodium* sp.) can also influence the release and content of infected host cell-derived EVs. These altered host cell-EVs have been implicated in inflammatory responses and in the modulation of immune

responses to the pathogen (Mantel and Marti, 2014; Twu and Johnson, 2014). Also during viral infection with herpes viruses or retroviruses, amongst others, virus-infected cells have an altered EV production profile in which EVs can contain both viral and cellular components. This heterogeneous population of EVs is involved in infection, either by enhancing or blocking of infection, or cause dysregulation of the immune response (Wurdinger *et al.*, 2012). Furthermore, viruses can recruit several components from the EV biogenesis routes and in this way viruses exploit the EV machinery for viral spread (Gould *et al.*, 2003).

In cancer there is accumulating evidence that tumor cell-derived EVs play a role in tumorigenesis, metastasis, and chemotherapeutic resistance (Tickner *et al.*, 2014). During tumorigenesis tumor-derived EVs deregulate antitumor immune responses by impeding both adaptive and innate immune responses (Zhang and Grizzle, 2011). Furthermore, these EVs modulate and restructure the local tumor environment and travel to distant sites to promote the formation of premetastatic niches (Psaila and Lyden, 2009). Tumor-derived EVs have also been implicated in the transfer of oncogenic activity (Al-Nedawi *et al.*, 2008) and in chemotherapeutic resistance (Al-Nedawi *et al.*, 2008). Also in many chronic inflammatory processes such as diabetes, rheumatic diseases, inflammatory bowel diseases, and allergic diseases, as well as in (cardio)vascular disease and neurodegenerative disorders, the role of EVs becomes more and more evident (EL Andaloussi *et al.*, 2013).

Clinical Applications of EVs

EV-Based Biomarkers

During the last 4–5 years it has become evident that body fluids (e.g., blood, urine, cerebrospinal fluid, and milk) contain large amounts of nano-sized (<200 nm) EVs originating from a variety of cell types. Since cells concurrently release different types of EVs and the molecular composition of EVs depends on the state of the releasing cell, EVs in body fluids are not only very abundant and heterogeneous but they also reflect the state of the cell of origin at the time of release. Consequently, during disease processes EVs in body fluids can contain important disease-related information. Indeed, tumor-derived EV signatures, based on microRNA, protein, or lipid content, have been defined in body fluids of cancer patients. In cancer patients where biopsy taking is not straightforward, the potential of EVs as so-called liquid biopsies is now widely investigated (Revenfeld *et al.*, 2014). In other diseases the detection of particular EVs has been associated with the onset of disease. For example, the excessive release of placental vesicles into the blood during pregnancy as an underlying cause of vascular damage and inflammation leading to the development of preeclampsia (Mincheva-Nilsson and Baranov, 2014). In general there is now broad interest in the identification and comprehensive characterization (cellular origin, composition, and concentration) of disease-associated EVs in body fluids (Figure 3).

Currently, clinical trials are under way in which the presence of coagulation-promoting tumor-derived EVs in the

Figure 3 Clinical perspectives of EVs. Since EVs are present in body fluids and the EV population changes during different (patho)physiological conditions, EVs offer a great potential as multifactorial biomarkers. EVs are also in the limelight as therapeutics, for example, MSC-derived EVs in the treatment of graft-versus-host disease patients. The special features of EVs are also exploited to engineer EV-based nano-carriers for drug delivery. For vaccine development EVs from pathogens and EVs from dendritic cells loaded with antigens derived from pathogens or tumors are currently studied.

blood of cancer patients is studied as a potential risk score marker to identify cancer patients at risk of developing venous thromboembolism (Zwicker *et al.*, 2013). Also for infectious diseases the analysis of pathogen-derived or infected cell-derived EVs in blood offers possibilities to monitor the infection status. Besides the disease-specific signature, EV-based biomarkers also have a great advantage in dealing with the enormous dynamic range of molecules present in body fluids to detect the frequently low-abundant diagnostic molecules. Altogether, EV-based biomarkers hold a great promise as prognostic, diagnostic, and therapeutic biomarkers in a wide variety of diseases. However, the process of identification of EV-based biomarkers is very arduous. A major limitation in this emerging field is the complicated isolation of EVs from complex body fluids such as blood which also contains high concentrations of lipoprotein particles with overlapping physical characteristics. Currently, there is a strong need for specialized and standardized isolation methods (Witwer *et al.*, 2013a). Furthermore, specific disease-associated EVs, such as tumor-derived EVs, are relatively rare events in the total EV population in blood in which the majority of EVs is derived from blood cells and vessels. Consequently, high throughput EV analysis is needed to identify subpopulations of disease-associated EVs. Unfortunately, most commonly used techniques either lack the sensitivity and specificity for individual EV-based analysis (e.g., conventional flow cytometry with a

detection limit of ~ 300 nm) or are low-throughput (e.g., electron microscopy and atomic force microscopy) (Momen-Heravi *et al.*, 2012). However, the recent achievements in high-resolution flow cytometry-based EV analysis are promising (Van der Vlist *et al.*, 2012). The great challenge for the coming years is to standardize protocols for EV measurements in body fluids and to develop translational technologies for robust analysis methods in clinical settings.

EV-Based Vaccines and Therapeutics

EVs derived from Gram-negative bacteria, i.e., OMVs, have been used in vaccine development since the late 1980s, and they are considered a safe and effective prevention method against *Neisseria meningitidis* infections (Figure 3). However, widespread application of OMV-based vaccines is hampered by several problems such as scale of production, lack of broad immunogenicity, and toxicity due to the presence of LPS (Baker *et al.*, 2014). However, the possibility to engineer these EVs to optimize their immunogenicity via incorporation of selected sets of bacterial antigens and to lower the toxicity and optimize the self-adjunct properties by LPS modifications makes them interesting candidates for vaccine development (Baker *et al.*, 2014). The knowledge of Gram-positive bacteria-derived EVs is still limited and their application as vaccine

remains to be elucidated. Besides prokaryotic cell-derived EVs also eukaryotic cell-derived EVs are studied for vaccine development (Figure 3). In 1998, the immune stimulatory potential of dendritic cell-derived EVs loaded with tumor antigens was revealed (Zitvogel *et al.*, 1998), and resulted in the first clinical trials in cancer patients in which the potential of these EVs as cancer vaccine was investigated (Escudier *et al.*, 2005). Nowadays also the vaccine potential of parasite-derived EVs or EVs from parasite-infected cells is explored (Martin-Jaular *et al.*, 2011).

EVs are also studied as therapeutic entity in regenerative medicine. Based on the regenerative capacity, mesenchymal stem cell (MSC)-derived EVs hold a great promise for repairing, replacing, restoring, or regenerating damaged cells, tissues, and organs (EL Andaloussi *et al.*, 2013). Furthermore, the immune suppressive properties of MSC-derived EVs may be used to dampen the immune system (e.g., during Graft-versus-host disease) (Figure 3). The application of EVs can resolve major safety issues related to uncontrollable dissemination and differentiation of transplanted cells, and since EVs are relative stable and easy to store they can overcome limitations associated with the use of viable cells. A current challenge for therapeutic application of EVs is to develop scalable manufacturing processes while maintaining the critical quality parameters (functionality, purity, and safety) of the final therapeutic product and to establish robust quality control criteria.

EVs also receive attention as nano-carriers for therapeutic entities because of their bioavailability, their low immunogenicity if derived from the appropriate cells (e.g., MSCs or immature dendritic cells), their specific targeting potential, and their resistance to metabolic processes (EL Andaloussi *et al.*, 2013; Johnsen *et al.*, 2014; Figure 3). The fact that EVs can cross classical borders, such as the blood-brain barrier, and can deliver small RNAs to regulate gene expression in targeted cells demonstrated the potential of targeted delivery via EV-based nano-carriers (Alvarez-Erviti *et al.*, 2011). In a rapidly increasing number of studies there is evidence that the loading of siRNAs and microRNAs in EV-based delivery systems prevent these RNA molecules from rapid degradation in the systemic circulation and results in functional transfer to the preferred target cells. However, in most studies classical cell transfection strategies-like electroporation and chemical transfection have been used to load the EV-based carriers. Besides the questionable efficacy of RNA loading, these methods can induce adverse effects on EV integrity or therapeutic cargo (Johnsen *et al.*, 2014). The alternative approach in which EV-producing cells are transfected with the therapeutic RNA is generally more effective in EV-RNA loading, but the cell engineering required to express a selected targeting protein on the EV surface of the RNA-loaded EVs is more laborious (Johnsen *et al.*, 2014). Also for the clinical application in which patient's own cells are used as EV source this is problematic. To optimize and secure reproducibility of EV-RNA loading efficiency, more insight in the physiological RNA loading mechanism of EVs is essential. Furthermore the development of non-autologous EV factory cell lines generating loaded EVs expressing the proper target moiety is of great interest. Besides the loading of RNA molecules, other types of therapeutic cargo have been loaded in EVs,

such as doxorubicin for the development of chemotherapeutic-EVs for cancer treatment. The *in vivo* targeted delivery of engineered EVs derived from dendritic cells greatly enhanced the efficacy of doxorubicin (Tian *et al.*, 2014). Although promising results are obtained in preclinical studies using EV-based vectors derived from dendritic cells and MSCs, many properties remain elusive. The fact that contradictory results can be obtained with EVs and EV-based vectors from the same cell type urges for prudence. The next steps in the development of EV-based therapeutics comprise the selection of optimal; (1) cell types as EV factory and culture conditions, (2) loading strategies for the desired therapeutic, (3) specific targeting moieties, (4) standardized EV isolation methods, and (5) full characterization of therapeutic EVs. Furthermore, up-scaling procedures of EV production and development of control procedures are needed. Although it is expected that EV-based therapeutics will evolve as a new field for clinical application, the hurdles to be overcome are not trivial.

Concluding Remarks

The increasing interest in EVs led in 2012 to the creation of a scientific society fully dedicated to the subject: the International Society of Extracellular Vesicles. Convincing evidence is present that EVs are an evolutionary conserved mechanism of intercellular communication allowing the exchange of complex information within and beyond organisms. Furthermore EVs hold a great promise as biomarker and therapeutic agent.

Nuclear Organization (Nuclear Structure and Dynamics)

Y Mimura and N Imamoto, RIKEN, Saitama, Japan

Introduction

In eukaryotic cells, unlike prokaryotic cells that contain naked DNA in their cytoplasm, chromosomes composed primarily of DNA and histones are wrapped with double lipid bilayers and are thus separated from the cytoplasm. This structure containing the genetic information is called the nucleus, and the double lipid bilayer wrapping the chromosomes is called the nuclear envelope (NE). The nucleus, in which essential cellular processes such as replication, transcription, and ribosome biogenesis are constantly occurring, is essential for basic cellular activities and for maintaining cellular homeostasis.

The NE is mainly composed of four components: the nuclear membrane, the nuclear pore complex (NPC), the nuclear lamina, and inner nuclear membrane (INM) proteins. The NE separates the nuclear contents from the cytoplasmic activities, which necessitates their mutual communication through the continuous exchange of molecules. The NPC, embedded in the NE, mediates nucleocytoplasmic molecular transport. The NE also plays a role in protecting genomic DNA from toxic metabolites produced in the cytoplasm, such as reactive oxygen species produced in mitochondria. Along with these functions, the NE is considered to regulate gene expression, DNA replication, and chromatin organization.

The nuclear interior is a well-ordered structure in which individual chromosomes are nonrandomly arranged into the particular nuclear space, termed as the chromosomal territory. Although the mechanism for the establishment of the chromosome territory remains elusive, the interaction between the chromosome and the NE is considered to play an essential role in the establishment of the chromosome territory. In addition, specialized domain structures, such as the nucleolus, Cajal body, and promyelocytic-leukemia nuclear body (PML-NB) are formed in the nuclear interior and dynamically interact with each other to coordinate nuclear functions.

Finally, it is also important to note that the nucleus is a dynamic structure. During the cell cycle, DNA in chromosomes must be replicated, and the replicated chromosomes must be precisely separated to transmit genomic information into daughter cells. Chromosome separation occurs during mitosis. In multicellular organisms, the nuclear structure is broken down at the mitotic entry. The NE–chromosome interaction is lost, and the NE is retracted into the endoplasmic reticulum (ER). The chromosomes are highly condensed, and a kinetochore is assembled on the centromere, which is a specific region in the chromosome. Centrosomes are duplicated in interphase, and mitotic microtubules form connections between the centrosome and kinetochore. Together with spatially and temporally well-orchestrated mitotic activities, such as kinases, phosphatases, nucleocytoplasmic transport machineries, and motor proteins, the chromosomes are segregated with the sophisticated machinery termed the mitotic spindle into the daughter cells. In late mitosis, the NE that was retracted into the ER is reassembled on the surface of

daughter chromosomes with the aid of protein–protein and protein–DNA interactions.

In this section, we briefly describe chromatin organization, the structure and function of the NE, and the mitotic dynamics of the nucleus.

Nuclear Structure and Function

Chromatin

All of the cells that compose our body contain the same base sequences of DNA in their nuclei. In humans, out of the entire genome, approximately 20 000 genes encode proteins. To generate the various organs such as brain or muscle from the fertilized egg that is a large single cell, gene expression must be regulated spatially and temporally through the developmental processes to build up specific gene expression patterns. To this end, cells potentially have many highly ordered and hierarchical mechanisms generating the diverse tissues via the structural alterations of the chromatin through histone exchange, posttranslational modifications of histones, and DNA modifications.

Eukaryotic DNA, whose length is approximately 2 m in human, is wrapped around cores of histone octamers that are composed of histone H2A, H2B, H3, and H4 (Luger *et al.*, 1997). In this way, all eukaryotic DNA is highly compacted in the nucleus. Histone H2A exclusively forms a heterodimer with histone H2B, while Histone H3 forms a heterodimer with Histone H4. A core histone octamer is assembled from two pairs of these heterodimers. The approximately 150 base pairs of DNA wrapped the core histone octamer is called a nucleosome, and it is the minimum module of chromatin structure. The nucleosome is formed in a stepwise manner. First, a pair of histone H3–H4 dimers wraps the DNA, and this intermediate is called a ‘tetrasome.’ Next, a pair of histone H2A–H2B dimers is further incorporated into the tetrasome and consequently matured into a complete nucleosome structure. These nucleosome assembly steps require the aid of a specific set of histone chaperones (De Koning *et al.*, 2007; Kurumizaka *et al.*, 2013).

Core histones without histone H4 contain many variants that are structurally distinct. Depending on the several cellular contexts (i.e., developmental processes, transcription, and DNA damage response), the core histones are dynamically and appropriately exchanged for other histone variants via specific histone chaperone activity. As a result of alterations of nucleosome structure via histone exchange, the cell can flexibly respond to internal and external stimuli (Volle and Dalal, 2014).

In addition to histone replacement, another important regulatory mechanism of chromatin for the response to many cellular processes is posttranslational modifications described as ‘epigenetics.’ Histone proteins can be structurally separated into the tail and core regions, and both regions contain many

Figure 1 Structure of metazoan nuclear envelope (NE). Schematic representation of the overview of NE. The nuclear pore complex is embedded in the NE composed of the inner nuclear membrane (INM) and the outer nuclear membrane (ONM). INM proteins containing LEM proteins, SUN1/2 and Lamin B receptor (LBR) exclusively localized to the INM. SUN1/2 and Nesprin form linker of nucleoskeleton and cytoskeleton (LINC) complex via SUN–KASH interaction, and connect the nucleoskeleton to cytoskeleton through their interaction. Heterochromatin is accumulated underneath the INM via the interaction with INM proteins and the nuclear lamina.

sites that accept various posttranslational modifications, particularly phosphorylation, acetylation, and methylation. DNA, especially cytosine residues, is also methylated via DNA methyltransferase activities. Many of these modifications of histones are reversible, but it remains unknown how methylated cytosine is eliminated from DNA (Cantone and Fisher, 2013). Epigenetic regulation through the posttranslational modifications of histones and DNA are considered to affect gene expression by altering the interactions between histones, DNA, nucleosomes, and other proteins, including DNA-binding proteins. Accommodative functions with both processes, histone exchange and DNA/histone modifications, are required mechanisms for development, homeostasis and inheritance (Sasaki and Matsui, 2008). Conversely, misregulation of these mechanisms is closely associated with several critical diseases, such as cancer and leukemia, as well as with aging (Greer and Shi, 2012; Chi *et al.*, 2010).

NE

Nuclear membrane

The nuclear membrane is comprised of two phospholipid bilayers. The membrane facing the cytoplasm is termed the outer nuclear membrane (ONM), and the membrane facing the nucleoplasm is termed the INM. The ONM continuously connects to the ER, and its surface, like that of the ER, is decorated with ribosomes. The INM accumulates specific sets of proteins collectively termed INM proteins, and A-type and B-type lamins construct the nuclear lamina underneath the INM. Many INM

proteins, either directly or through association with lamins, interact with chromatin. The ONM is fused with the INM at sites termed pore membrane at which the NPC is present. The NE functions as the physical barrier that protects the nuclear interior from the cytoplasmic activities (Figure 1).

Nuclear lamina

In metazoans, the nuclear lamina, which is a meshwork structure, is composed of two types of lamin proteins termed A-type and B-type lamins. Both A-type and B-type lamins belong to the type V intermediate filaments (IFs), and the nuclear lamina confers physical strength to the NE. Interestingly, lamins are highly evolutionarily conserved in metazoans such as vertebrates but are not conserved in plants and yeast. Lamin A, Lamin C, Lamin C2, and Lamin AΔ10 belong to the A-type lamins and are encoded by the single *LMNA* gene (Burke and Stewart, 2013), while Lamin B1 and Lamin B2 belong to the B-type lamins and are encoded by separate genes, *LMNB1* and *LMNB2*, respectively. Lamin C is a C-terminus truncated form of Lamin A from an alternative splicing of the *LMNA* product. At least one form of B-type lamin is expressed in each cell, whereas the expression of A-type lamins is regulated in tissue-specific and development-dependent manners.

Both A-type and B-type lamins share the same structural features, including head and α -helical rod domains in the N-terminus. Although all tail regions in Lamin proteins contain the nuclear localization signal (NLS), their tail regions show structural differences. After translation, Lamin proteins mature through a series of posttranslational processes. The carboxy-terminals of Lamin A, Lamin B1, and Lamin B2, but

not Lamin C, contain the CAAX motif that is also conserved in the Ras superfamily (C: Cysteine, A: aliphatic amino acid, X: any amino acid). Initially, cysteine residues in these motifs of pre-Lamins are posttranslationally modified by farnesyl-transferase (FTase) that transfer the 15-carbon farnesyl lipid to cysteine, and the isoprenyl groups are transferred to its side chain (Roskoski, 2003). These posttranslational modifications require the presence of Zn^{2+} and Mg^{2+} ions. Following the isoprenylation, pre-Lamin A is cleaved at the carboxy-terminal end of the isoprenylcysteine residue in this motif by zinc metalloprotease ZMPSTE24, which is embedded in the NE/ER membrane via its 7-transmembrane regions and specifically recognizes the isoprenylcysteine residue (Quigley *et al.*, 2013; Pryor *et al.*, 2013). Meanwhile, pre-Lamin B is cleaved via farnesylated proteins-converting enzyme2 (FACE2) at the same site as pre-Lamin A. After removing the AAX tripeptide, isoprenylcysteine residues in the carboxyl terminal of a pre-Lamins becomes methylated via isoprenylcysteine carboxyl methyltransferase (ICMT) that also contain the multi-transmembrane regions and is embedded in the ER membrane (Winter-Vann and Casey, 2005). It is hypothesized that this isoprenyl group on Lamin B1 and B2 aids the Lamin B-phospholipid membrane attachment via a hydrophobic interaction. Only pre-Lamin A undergoes secondary digestion via ZMPSTE24 on the INM, leading to the removal of the 15 polypeptides in its carboxy terminal, including the isoprenylated cysteine. This series of processes produces mature Lamin A.

Both A-type and B-type lamins form homodimers as minimum modules for the construction of the nuclear lamina via α -helical coiled-coil regions within a rod domain. Similar to other IF family proteins, filament-like structures are formed by head-to-tail self-association of these homodimers both *in vivo* and *in vitro*. The precise overall structure and organization of the nuclear lamina is, however, an ongoing debate (Burke and Stewart, 2013). The nuclear lamina certainly provides the platform for a specific set of integral-membrane proteins, termed INM proteins, and specific DNA domains, termed lamin-associated domains (LAD).

Several human diseases associated with NE components, including both lamins and INM proteins, are collectively called 'laminopathies' (see also INM proteins section). Compared with *LMNB1* and *LMNB2*, a huge number of mutations in *LMNA* have been reported to be associated with laminopathies. Depending on the specific mutation, patients harboring mutations in *LMNA* associated with laminopathies show various symptoms, including cardiomyopathy, muscular dystrophy, lipodystrophy, mandibulofacial dysplasia, and progeria syndrome. One of the most famous and characterized *LMNA*-associated laminopathies is Hutchinson-Gilford progeria syndrome (HGPS) (Butin-Israeli *et al.*, 2012). Patients with HGPS show various clinical manifestations including premature aging, loss of subcutaneous fat, and atherosclerosis. Cells derived from HGPS patients express an abnormal Lamin A protein called progerin, which is an immature Lamin A protein containing an uncleaved farnesyl group in its C-terminus, due to a point mutation in the *LMNA* gene (C1828T). Although the progerin protein shows normal localization to the INM, cells from HGPS patients show nuclear blebbing and biological activity defects such as the loss of heterochromatin,

accumulation of DNA damage, and premature senescence. It is considered that these cellular defects are caused by the expression of 'farnesylated progerin' because FTase inhibitors can inhibit these cellular defects in HGPS patients.

NPC

The NPC, one of the largest protein complexes in the cell, has structurally and functionally well-conserved architecture in eukaryotic cells from yeast to mammals. The NPC is assembled from approximately 30 distinct proteins termed nucleoporins (Nups), and it has an eight-rotational asymmetric structure forming a tunnel between the cytoplasm and the nucleoplasm (Figure 2). The hollow space in the NPC structure is filled with many disordered/unstructured polypeptides containing hydrophobic amino acids, collectively called FG repeats (phenylalanine glycine repeats). This hollow is called the central channel, which is a site of the nucleocytoplasmic trafficking of molecules. Relatively small molecules of less than 50 kDa can freely pass through the NPC, while larger molecules above 50 kDa cannot do so. This size-dependent exclusion mechanism of the NPC is called a 'permeability barrier,' and the hydrophobicity in the central channel plays an essential role in the molecular transport that is a fundamental function of the NPC. In general, macromolecules containing specific amino-acid signal sequences, the NLS and the nuclear export signal (NES), can pass through the NPC in a nuclear transport receptor (NTR)-dependent manner.

Nups can be roughly categorized into four broad types by their structural roles: scaffold Nups, transmembrane Nups, central Nups, and peripheral Nups. Several Nups comprises subcomplexes throughout the cell cycle. For example, in mammalian cells, one of these subcomplexes, the NUP107-160 subcomplex, is composed of NUP107, NUP160, NUP133, NUP96, NUP75, NUP43, NUP37, Seh1, and Sec13, and the other, the NUP93-205 subcomplex, is composed of NUP93, NUP205, NUP188, NUP155, and NUP53. The NUP107-160 subcomplex has a Y-shaped structure, and it forms ring-like substructures at both the nucleoplasmic and cytoplasmic sides (termed the nucleoplasmic ring and the cytoplasmic ring, respectively). The NUP93-205 subcomplex is also assembled in a ring-like substructure, termed a spoke-ring complex, that adjoins the cytoplasmic and nucleoplasmic rings. The spoke-ring complex anchors the central Nups to form the central channel (Grossman *et al.*, 2012).

Transmembrane Nups, NDC1, POM121, and GP210 in mammalian cells, contain transmembrane regions and are embedded into the pore membrane. Because transmembrane Nups have an affinity for both NUP107-160 and NUP93-205 scaffold subcomplexes, this group of Nups is considered to anchor scaffold substructures to the pore membrane.

Central Nups, which consist of NUP54, NUP58, and NUP62, form a subcomplex and play a critical role in the formation of the central channel. These three Nups contain FG repeats and confer the relatively hydrophobic environment to the central channel. This hydrophobicity of the central channel plays the central role in the establishment of the permeability barrier and macromolecular transport.

Other Nups are categorized as peripheral Nups. This group of Nups is also associated with the establishment of the permeability barrier and molecular transport because of FG-repeat

Figure 2 Metazoan nuclear pore complex (NPC) components. Schematic representation of the distribution of Nups within the NPC. Scaffold Nups and transmembrane Nups are indicated with red and green colors, respectively. Central Nups and peripheral Nups are indicated with blue and gray colors, respectively. The peripheral Nups that associate with cytoplasmic filament and nuclear basket are indicated with brown color. Note that this Nups distribution within the NPC is experimentally predicted model so far.

containing peripheral Nups. These Nups form two types of substructures on both the cytoplasmic and nucleoplasmic sides: cytoplasmic fibrils and nuclear baskets. Cytoplasmic fibrils are filamentous structures that are mainly composed of NUP358/RanBP2. Nuclear baskets are basket-like structures that are mainly composed of NUP153 and TPR. Both substructures participate in the regulation of transport receptor-dependent macromolecular exchange (Hoelz *et al.*, 2011).

In proliferating cells, NPCs are constantly assembling throughout the cell cycle. At the mitotic entry, NPCs are highly phosphorylated via several mitotic kinases, and they are consequently broken down into subcomplexes (see section NE disassembly and reassembly in Mitosis). After the onset of anaphase, Nups are dephosphorylated via protein phosphatases (PPases), and they then assemble into NPCs on the surface of daughter chromosomes. This process is termed

‘post-mitotic NPC assembly’ (Wandke and Kutay, 2013). By contrast, during interphase, NPCs are embedded in the growing and closed NE. For this reason, the INM and ONM must be fused via unknown mechanisms to form the pore membrane (Rothballer and Kutay, 2013).

INM proteins

INM proteins (also called as nuclear envelope transmembrane (NET) proteins) are defined as preferentially INM-localized proteins, and they contain several transmembrane regions. The INM proteins construct the nuclear lamina together with the nuclear lamins. The total number of INM proteins is reported as nearly 200 proteins, and the number of identified INM proteins continues to increase (Wilson and Berk, 2010; Berk *et al.*, 2013). Most INM proteins remain uncharacterized, and only a small number of INM proteins have been thoroughly

investigated. The INM proteins that have been investigated interact with either A-type lamin, B-type lamin or both, and they regulate processes including heterochromatin positioning, signal transduction, and the nucleo-cytoskeleton via protein–protein and protein–DNA interactions (Wilson and Foisner, 2010). The interaction between INM proteins and the nuclear lamina contribute, at least in part, to the retention of INM proteins at the INM.

The lamina-associated polypeptide (LAP) family was originally defined as integral-membrane proteins that localize to the INM and bind to the nuclear lamina (Senior and Gerace, 1988). Presently, LAP family proteins also include nuclear lamina-binding proteins that do not contain transmembrane regions, such as LAP2 α (Wilson and Foisner, 2010), but all LAP family proteins are localized to the INM.

Other characterized nuclear lamina-binding proteins contain LEM (LAP2, Emerin, MAN1) domains, which directly interact with a protein called Barrier to Autointegration Factor (BAF). BAF binds with DNA with high affinity, and it also binds with core histones, linker histones, nuclear lamina proteins, and BAF itself (Margalit *et al.*, 2007). LEM domain proteins therefore interact with chromatin through BAF, and they also interact with chromatin directly. Because of these properties, LEM domain-containing proteins play an important role in anchoring the INM to chromatin. Another chromatin-anchoring INM protein is Lamin B receptor (LBR). LBR is a transmembrane protein that contains an N-terminal nucleoplasmic region and eight membrane-spanning regions (Olins *et al.*, 2010). LBR constantly associates with B-type Lamins via its N-terminal nucleoplasmic region. In addition to its interaction with B-type Lamin, the N-terminal nucleoplasmic region also interacts with components of heterochromatin such as core histones, heterochromatin protein 1 (HP1), and heterochromatin methyl-binding protein 1 (MECP1).

Importantly, the nuclear lamina is linked with microtubules and actin filaments present in the cytoplasm. The skeletal structures of the nucleoplasm (nucleoskeleton) and cytoplasm (cytoskeleton) are linked through a protein complex called linker of nucleoskeleton and cytoskeleton (LINC) complex. This connection between the nucleoskeleton and the cytoskeleton is important for the intracellular positioning of the nucleus, centrosome tethering, the regulation of the distance between the INM and ONM, and the transduction of extracellular mechanical stress. The LINC complex is composed of SUN (Sad1 and UNC-84) domain-containing proteins on the INM and KASH (Klarsicht, ANC-1, Syne homology) domain-containing proteins on the ONM. In mammals, at least five SUN domain-containing proteins have been discovered: SUN1, SUN2, SUN3, SUN4/SPAG4, and SUN5/SPAG4L. Among these proteins, SUN3 and SUN4/SPAG4 and SUN5/SPAG4L show tissue-specific expression in the testis (Sosa *et al.*, 2013). SUN1 and SUN2 each contain a single transmembrane domain and a C-terminal SUN domain, which is located in the luminal region of the NE. SUN1 and SUN2 are exclusively localized to the INM, and they directly bind to Lamin A at the nucleoplasmic side. In mammals, six KASH domain-containing proteins have been reported; among them, NE spectrin-repeat proteins 1–4 (Nesprin1–4) are well characterized for LINC complex formation. Nesprin proteins

interact with cytoplasmic actin, microtubules, centrosomes, or IFs via the long N-terminal cytoplasmic region that contains a large number of spectrin repeats (Rajgor and Shanahan, 2013). After the spectrin repeats, all Nesprin proteins contain a single transmembrane region and a luminal KASH domain in their C-termini. In the luminal region in the NE, the SUN domain rigidly and stably binds with KASH domain, thereby forming the LINC complex (Horn, 2014).

Laminopathies are also caused by the mutation of genes encoding lamin-associated proteins. Patients harboring mutations in the *Emerin* gene show X-linked Emery-Dreifuss muscular dystrophy (X-EDMD), and mutations in *SYNE1* or *SYNE2*, encoding Nesprin1 and Nesprin2, respectively, also induce EDMD (Horn, 2014). Other mutations in the *Emerin* gene cause limb-girdle muscular dystrophy, cardiomyopathy, or familial atrial fibrillation (Wilson and Foisner, 2010). The LEM domain-binding protein BAF causes Nestor-Guillermo progeria syndrome (Berk *et al.*, 2013), and LBR mutations are associated with hydrops-ectopic calcification-moth-eaten/Greenberg skeletal dysplasia and Pelger–Huët anomaly.

NE Disassembly and Reassembly in Mitosis

‘Open’ and ‘closed’ mitosis

Mitosis is the most important cellular process for dividing cells. The genetic information in the eukaryotic nuclei must be accurately transmitted to daughter cells by the mitotic spindle, which is mainly composed of microtubules and centrosomes. The mitotic spindle is generally assembled such that the microtubules, extending from the centrosomes and other microtubule-organizing centers, capture the kinetochores formed at the centromeres of mitotic chromosomes (O’Connell and Khodjakov, 2007).

Eukaryotic cells have two general styles of mitosis. One is ‘closed mitosis,’ in which the NE is sustained through mitosis, and the other is ‘open mitosis,’ in which the NE is completely broken down (Fernandez-Martinez and Rout, 2009; Sazer *et al.*, 2014). Yeast cells exhibit closed mitosis. They embed the spindle pole body (SPB), the microtubule-organizing center, in the NE. This allows mitotic spindle assembly in yeast without NE breakdown (NEBD). By contrast, in multicellular organisms that exhibit open mitosis, the microtubule-organizing center, the centromere, resides in the cytoplasm. In these cells, the NE must be broken down at the onset of mitosis so that the kinetochores can be captured by the microtubules extending from the centromeres. In late mitosis, the NE that was broken down must be reassembled on the surface of segregated daughter chromosomes (Anderson and Hetzer, 2008; Wandke and Kutay, 2013).

RanGTP gradient in interphase and mitosis

During interphase, large numbers of macromolecules are bidirectionally transported between the cytoplasm and the nucleus by NTRs such as the importin β superfamily (Clarke and Zhang, 2008). This bidirectional macromolecular transport is driven by the small GTPase Ran. The GTP-bound form of Ran (RanGTP) is concentrated at the nuclear interior, where the nucleotide exchange factor regulator of chromosome condensation 1 (RCC1) exclusively binds to chromatin and

Figure 3 Importin α/β and Ran system in Interphase and Mitosis. (a) RanGTP and NTRs spatially regulate the spindle microtubule assembly via binding of spindle assembly factors (SAFs) to chromosome. (1) SAF harboring the nuclear localization signal (NLS) is recognized with nuclear transport receptor (NTR) such as Importin α/β , and they form a transport complex. The interaction of SAF (in this case, Tahara, K., Takagi, M., Ohsugi, M., *et al.*, 2008. Importin- β and the small guanosine triphosphatase Ran mediate chromosome loading of the human chromokinesin Kid. *Journal of Cell Biology* 180, 493–506) with NTR inhibits SAF's chromatin binding activity. (2) and (3), When the transport complex reaches mitotic chromosome, its disassembly is triggered by GTP-bound form of Ran (RanGTP) bound to NTR. (4) SAF released from transport complex accumulates on the chromosome, and promotes the spindle formation. RanGTP is constitutively generated via RCC1 residing on chromosomes, thus high concentration of RanGTP exists at the vicinity of chromosomes. (b) RanGTP and NTRs regulate the nuclear import of cargo proteins harboring the NLS. (1) By the same rule as (a), the cargo protein is recognized by NTRs, and they form a transport complex. (2) The transport complex passes through the nuclear pore complex (NPC), and enters the nuclear interior. (3) At the nuclear interior, RanGTP binds to the NTR and triggers disassembly of the transport complex. As a result, the cargo protein is released from the complex. (4) After releasing the cargo, the NTR binds to RanGTP and exits the nucleus through NPC. (5) In cytoplasm, GTPase activity of RanGTP bound to NTR is activated by the aid of RanGAP. Consequently, GTP on Ran is immediately hydrolyzed into GDP. (6) RanGDP generated by RanGAP in the cytoplasm is recognized by NTF2, and is imported into the nucleus. At the nuclear interior, GDP on Ran is replaced by GTP by RCC1 activity.

constantly replaces GDP with GTP on Ran. In the cytoplasm, RanGAP1 (RanGTPase-activating protein 1), which is exclusively localized to the cytoplasmic side of the NPC, facilitates the GTPase activity of Ran, and GTP on Ran is hydrolyzed to GDP. The GDP-bound form of Ran (RanGDP) in the cytoplasm is imported into the nucleus by nuclear transport factor 2 (NTF2). As a result, the concentration of RanGTP is higher in the nucleus than in the cytoplasm. When a cargo macromolecule containing an NLS is imported into the nucleus, it binds to a nuclear import receptor and then passes through the NPC. At the nuclear interior, RanGTP binds to the cargo-bound nuclear import receptor, thereby inducing cargo release into the nucleoplasm. Conversely, when a cargo macromolecule containing an NES is transported from the nucleus into the cytoplasm, the cargo interacts with the nuclear export receptor and RanGTP in the nucleus, forming the export complex. After passing through the NPC, RanGAP1 hydrolyzes

GTP on Ran to GDP in the cytoplasm, and the export complex consequently disassembles (Guttler and Gorlich, 2011; Figure 3).

During mitosis, although the NE, including the nuclear lamina and the NPC, is broken down, RCC1 remains to bind mitotic chromosomes. The action of RCC1 produces a high concentration of RanGTP around the mitotic chromosomes. The concentration of RanGTP gradually decreases toward the plasma membrane (Kalab *et al.*, 2006). As in interphase, the RanGTP gradient drives cargo release and binding to NTR during mitosis. Therefore, NLS-containing spindle assembly factors (SAFs) such as TPX2 and KID bind to nuclear import receptors in the mitotic cytoplasm. In the vicinity of mitotic chromosomes, SAFs are released from nuclear import receptors and become loaded onto mitotic chromosomes because of the high concentration of RanGTP. Many SAFs are associated with microtubule nucleation, stabilization and elongation; therefore,

the RanGTP gradient around mitotic chromosomes during mitosis forms a spatial context for regulating mitotic spindle assembly (Fuller, 2010; Kalab and Heald, 2008). In addition to mitotic spindle formation, the mitotic RanGTP gradient is also associated with the NE reassembly during late mitosis.

NE disassembly and reassembly

When the cell enters open mitosis, the entire NE structure, including the nuclear lamina, NPC, and nuclear membrane, must be disrupted for proper formation of the mitotic spindle. In this context, it is considered that phosphorylation by mitotic kinases is at least one of the key processes to disassemble the NE. The proteins forming the NE are directly phosphorylated via mitotic kinases including cyclin-dependent kinase1 (CDK1)-CyclinB, Polo-like kinase1 (PLK1), Protein kinase C (PKC), Aurora A and Aurora B. As initial phosphorylation targets in late prometaphase, peripheral FG repeat-containing Nups such as NUP98 become phosphorylated, before the phosphorylation of scaffold Nups, by multiple mitotic kinases including CDK1-CyclinB, disrupting the permeability barrier of NPCs (Laurell *et al.*, 2011). Consequently, cytoplasmic proteins leak into the nuclear interior and accelerate the NEBD. The lamins are also phosphorylated and depolymerized via CDK1-CyclinB activity at the mitotic entry. The LEM domain-binding protein BAF is phosphorylated via Vaccinia-related kinase (VRK) during mitosis. Phosphorylation of BAF by VRK causes the loss of its DNA-binding activity and reduces its interaction with Emerin (Margalit *et al.*, 2007). LBR is phosphorylated by mitotic kinases in its N-terminal region and loses its heterochromatin-binding activity. For proper progression of the NEBD, such phosphorylation-dependent attenuation of the interactions between INM proteins–chromatin might be essential. Furthermore, the cytoplasmic microtubules also support the destruction of the NE through their pulling force (Guttinger *et al.*, 2009).

After the onset of anaphase, PPases such as PP1 $\alpha/\beta/\gamma$ and PP2A/B are relatively active, whereas net kinase activities gradually decrease (Wurzenberger and Gerlich, 2011). The activated PP1 dephosphorylates the mitotically phosphorylated NE components. These dephosphorylation processes are associated with the NE reassembly. In late anaphase, the nucleosome-binding Nup ELYS is dephosphorylated, and it is then targeted to the surfaces of daughter chromosomes that are segregated by the mitotic spindle. Following the targeting of ELYS, the NUP107-160 subcomplex and POM121 are recruited to the chromosome surface. As a result, the complete NPC structure is built up on the daughter NE. BAF phosphorylated by VRK is dephosphorylated via PP2A, consequently restoring its ability to bind to both chromatin and LEM domain proteins (Asencio *et al.*, 2012). LBR can also become bound to components of heterochromatin upon its dephosphorylation. Such chromatin-binding activity of INM proteins through dephosphorylation is required for the re-formation of the NE in daughter cells (Clarke and Zhang, 2008).

Conclusion

In this section, we described the nuclear organization with a focus on the structures of chromatin and NE in interphase, as well as the mitotic dynamics of the NE. Through the cell

cycle, the chromatin structure is dynamically altered via post-translational modifications and histone exchange depending on both internal and external stimuli. In eukaryotic cells during interphase, the NE is the physical barrier protecting chromatin against numerous cytoplasmic toxic metabolites such as reactive oxygen species. The NE is also critical for the establishment of the macromolecular nucleocytoplasmic transport system that is operated by the NPC and diverse NTRs. The INM provides the sites in which heterochromatin is anchored via the interaction with the nuclear lamina, which is composed of lamins and INM proteins. By contrast, in cells demonstrating open mitosis, the NE is disassembled at the mitotic entry through mitotic kinase activities that allow chromatin segregation via microtubules. These cells reassemble the NE at late mitosis by the coordinated inactivation of mitotic kinases and activation of PPases. RanGTP and Importin β , which mediate nucleocytoplasmic transport in interphase, are required for assembling the mitotic spindle, chromosome segregation and NE formation, processes important for the inheritance of the mass of chromatin by daughter cells.

During the past decade, a number of NE proteins have been identified, along with their modifications and interactions (protein–protein, protein–DNA, protein–RNA), advancing our understanding of the structure and function of the NE itself. However, because the NE is tightly related to many cell biological processes involving cellular metabolism, cytoskeletons, and the nuclear genome, we require further clues to understand NE organization and dynamics in the context of its connections to a variety of cellular physiological processes.

Structure of the Nuclear Pore Complex

The morphology of nuclear pore complex (NPC) has been studied intensively using electron microscopy (EM) (Callan and Tomlin, 1950; Gall, 1967; Maul, 1971) and cryo-electron microscopy (Akey and Radermacher, 1993; Yang *et al.*, 1998; Stoffer *et al.*, 2003; Beck *et al.*, 2004). Recent studies with cryo-electron tomography shows a 3D model of NPCs with ~6-nm resolution (Frenkiel-Krispin *et al.*, 2010; Beck *et al.*, 2007). The NPC shows an eightfold rotational symmetry to its central axis. There are three major octagonal rings connected by spokes, which form the core scaffold of the NPC. Specifically, they are called cytoplasmic ring, central spoke ring, and nuclear ring. The central channel located in the middle provides the NPC's function as a selective permeable barrier. There are elongated filamentous structures found asymmetrical in the cytoplasmic and nuclear sides of the NPC. Eight of these filaments extend from cytoplasmic ring into the cytoplasm, while the nuclear filaments extending from nuclear ring are connected at their ends forming a basket-like structure (Figure 1).

Even though the size of the NPC varies from ~66 MDa in yeast (Rout and Blobel, 1993) to ~125 MDa in vertebrates

(Reichelt *et al.*, 1990), its structural feature is conserved across species (Hinshaw *et al.*, 1992; Akey and Radermacher, 1993; Yang *et al.*, 1998; Grossman *et al.*, 2012).

NPCs are composed of approximately 30 different proteins, called nucleoporins (Nups), which are conserved among eukaryotes (Rout *et al.*, 2000; Cronshaw *et al.*, 2002; DeGrasse *et al.*, 2009; Tamura *et al.*, 2010).

Nucleoporins (Nups)

Nups can be classified according to their sequence motifs, structural folds, mobility, or relative localization within the NPC (Rout *et al.*, 2000; Tran and Went, 2006; Hoelz *et al.*, 2011; Grossman *et al.*, 2012). An example of Nup-classification is (1) membrane Nups, (2) scaffold Nups, and (3) peripheral Nups.

One characteristic sequence motif/structural folds of Nups is the tandem repeats of phenylalanine-glycine (FG repeats), which are unfolded in native protein (Denning *et al.*, 2003). These FG repeats are found in approximately one-third of Nups (also called as FG-Nups), mostly belonging to the peripheral Nups. Most of these FG repeats are further classified

Figure 1 The structure of nuclear pore complex (NPC). Nups consist of each structural component are depicted in the box. There are three major rings (cytoplasmic ring, central spoke ring, and nuclear ring) forming the core scaffold, which is anchored to the nuclear membrane by transmembrane Nups. The cytoplasmic filaments are extending from the cytoplasmic ring into the cytoplasm, while the nuclear filaments extending from nuclear ring are connected at their ends forming a basket-like structure. The central channel is filled with central FG-Nups, which provides the function of NPC as a selective permeable barrier.

into either Phe-Gly (FG), Gly-Leu-Phe-Gly (GLFG), or Phe-any-Phe-Gly (FXFG) (Rout and Wente, 1994).

FG-Nups located in the central channel of NPC (central FG-Nups) are important for barrier formation, which inhibits the passive diffusion of macromolecules through the NPC. Furthermore, FG-Nups can bind to nuclear transport factors (Radu *et al.*, 1995; Rexach and Blobel, 1995; Hu *et al.*, 1996; Clarkson *et al.*, 1996; Bayliss *et al.*, 2000), which is important for the active transport process of selected molecules. Indeed, nanotube coated with FG-Nups can selectively allow the transport of karyopherin or karyopherin-cargo complexes (Jovanovic-Talisman *et al.*, 2009); moreover, some of these FG-Nups can form hydrogels *in vitro* that selectively allow the influx of transport factors (Frey and Gorlich, 2007; Hulsman *et al.*, 2012). Thus, FG-Nups are important for selective translocation of transport factor-cargo complexes through the NPC.

The property of this 'selective permeability barrier' of NPC is presumably attributed to either the highly dense unfolded FG domains which function as entropic bristles for macromolecules (Rout *et al.*, 2003; Lim *et al.*, 2006) which also can be collapsed upon karyopherin binding (Lim *et al.*, 2007) or the formation of cohesive meshwork through self- or inter-FG-Nup interaction (Ribbeck and Gorlich, 2001; Alber *et al.*, 2007) or hybrid of them (Patel *et al.*, 2007; Yamada *et al.*, 2010). Even though there are several sophisticated molecular models postulated to explain the mechanism of nuclear transport through the NPC, including those mentioned above, the exact molecular mechanism remains to be established (Walde and Kehlenbach, 2010; Grunwald *et al.*, 2011).

Structural Nups or scaffold Nups are important for the formation of the scaffold of NPC, and they can interact both with FG-Nups and transmembrane Nups. Almost half of Nups belongs to this group, and many of these structural Nups are contained at the inner, outer ring (nuclear ring and cytoplasmic ring) structures, central spoke ring, and linker connecting these rings. Structural Nups often contain α -solenoid fold and/or β -propeller fold. Of these, one structural complex termed Y-complex (known as Nup84 subcomplex in yeast and Nup107/160 subcomplex in vertebrates), named after its shape observed in EM (Siniosoglou *et al.*, 2000; Lutzmann *et al.*, 2002) has been well characterized. Interestingly, the structure of Y-complex shows similarity to COPII coated vesicle complexes, which also contain α -solenoid fold and β -propeller protein domains, thus, suggesting that NPC and coated vesicle might originate from the same ancestor (Devos *et al.*, 2004; Brohawn *et al.*, 2008).

Transmembrane nucleoporins anchor the NPC to the nuclear membrane. This group of Nups mainly consists of three members both in yeast (Pom34, Ndc1, and Pom152) and metazoa (gp210, Ndc1, and POM121). These transmembrane Nups were also suggested playing important roles in assembly/disassembly of NPCs (Guttinger *et al.*, 2009).

Dynamic Behavior of Nucleoporin

NPCs are not static structures playing a role as gateways in the nucleocytoplasmic transport system, but also show dynamic properties. Indeed, some of the peripheral Nups can get away

from NPC, as mobile Nups, they can actively participate in the nucleocytoplasmic transport (Tran and Wente, 2006) and be involved in other cellular processes, such as gene regulation, chromatin organization, mitotic spindle assembly, or DNA repair (Suntharalingam and Wente, 2003; Strambio-De-Castillia *et al.*, 2010).

A study showed that mammalian peripheral (mobile) Nups, such as Nup50 and Nup153, reside within the NPC for a short period of time (seconds scale), but stable scaffold Nups including Nup107 and Nup133, can remain within the NPC for days (Rabut *et al.*, 2004). Furthermore, these scaffold Nups are assumed to be one of the most stable proteins in a cell (Savas *et al.*, 2012).

These dynamic properties are also observed during open mitosis, in which the NPCs are disassembled into subcomplexes, which occurs in most multicellular organisms. At the end of mitosis, those subcomplexes assemble within the nuclear envelope formed around chromatin.

Nucleocytoplasmic Transport

NPCs are the sole gateway of nucleocytoplasmic transport. Small molecules, such as ions, metabolites, or peptides, can pass through the NPCs via passive diffusion; however, macromolecules, such as protein (larger than approximately 40 kDa) and RNA, are transported from cytoplasm into nucleus (import) or transported from nucleus into cytoplasm (export) in an energy-dependent process. Furthermore, even a macromolecule with a diameter of approximately 39 nm can pass through the NPC (Pante and Kann, 2002).

These active transports are generally mediated via transport receptors called karyopherin (or importin or exportin, termed their properties) (Hicks and Raikhel, 1995; Gorlich and Mattaj, 1996; Yoneda, 2000). The cargo protein macromolecules contain nuclear localization signal (NLS) or nuclear export signal (NES) or both, and those are recognized by specific subsets of karyopherin families, depending on their NLS or NES signal sequences. Karyopherins can bind to various FG-Nups with low affinity, and that causes the selective and efficient translocation of cargo in and out of the nucleus.

In case of RNAs, either karyopherin directly binds to RNAs (tRNA or miRNA) or indirectly via RNA-binding adapter proteins (mRNA in the form of messenger ribonucleoprotein particle) (Kohler and Hurt, 2007).

The direction of active nucleocytoplasmic transport is mainly determined by small GTPase RanGTP-GDP cycle. Ran exists as in GTP-bound form (RanGTP) or GDP-bound form (RanGDP). While a nucleotide exchange factor for Ran, RCC1, localizing in the nucleus catalyzes the formation of RanGTP (Bischoff and Ponstingl, 1991), a GTPase activating protein for Ran, RanGAP (Bischoff *et al.*, 1994), RanBP1 and RanBP2 localizing in the cytoplasm hydrolyze them into RanGDP (Gorlich *et al.*, 1996; Bischoff *et al.*, 1995). Thus, this compartmentalized distribution of RanGTP-GDP cycle regulators cause the creation of a keen asymmetric nucleocytoplasmic ratio of RanGTP/RanGDP, called Ran gradient. While importin-cargo complex can be disassembled in the presence of RanGTP in the nucleus, exportin-cargo complex can be formed only in the presence of RanGTP. Therefore, nuclear

Figure 2 The mechanism of nucleocytoplasmic transport of proteins. Importin binds to the cargo proteins through NLS in the cytoplasm. After translocation into the nucleus, binding of RanGTP to importin cause the disassembly of the cargo (NLS)-importin complex. On the other hand, exportin binds to the cargo proteins through NES in the presence of RanGTP in the nucleus, then, carried into the cytoplasm. The hydrolysis of RanGTP into RanGDP in the cytoplasm cause the disassembly of cargo(NES)-exportin-RanGTP complex. Cargo-free importin or exportin can shuttle back into the cytoplasm or nucleus, respectively.

RanGTP directs the orientation of transport processes (Figure 2).

Nucleoporin and Disease

The malfunction of nucleoporin has been linked to diseases. A mutation that affects the subcellular localization of Nup155 or ALADIN is known to cause cardiac disease (Zhang *et al.*, 2008) or triple-A syndrome (a rare disease characterized by alacrima, achalasia of the esophageal cardia, and adrenal failure) (Tullio-Pelet *et al.*, 2000; Cronshaw and Matunis, 2003; Handschug *et al.*, 2001), respectively. Nucleoporins, such as Nup214, Nup98, Nup358, or Tpr, form Nup-fusion genes with various partner genes in malignancies, and those possess oncogenic activities (Cronshaw and Matunis, 2004; Capelson and Hetzer, 2009; Xu and Powers, 2009). Of these, Nup98 is known to fuse with ~30 different partner genes, whose physiological functions are diverse, as seen in leukemia (Gough *et al.*, 2011; Nakamura *et al.*, 1996). However, it remains unknown

whether these diverse Nup98-fusions share the same mechanism of pathogenesis.

Collectively, these facts suggest that unregulated nucleocytoplasmic traffic of specific subsets of cargo may induce the disease of various types.

Plastids: The Anabolic Factories of Plant Cells

RR Wise, University of Wisconsin Oshkosh, Oshkosh, WI, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

Chloroplasts are photosynthetic organelles found in plant cells. Indeed, the very definition of what it means to be a plant is largely predicated on their photoautotrophic abilities, which reside exclusively in the chloroplast. However, chloroplasts are only one member of the plastid family, a diverse, phylogenetically and ontogenetically related group of organelles (Kirk and Tilney-Bassett, 1967). Depending on the breadth of the definition, there are as many as 20 distinctly different types of plastids found in both plants and animals (Wise, 2006). The seven main plastid types found in green plants (members of the clade Viridiplantae; Figure 1) will be considered in this encyclopedia article to illustrate the wide diversity of anabolic activities of which plastids are capable – well beyond the basic, life-supporting process of photosynthesis.

Substantial evidence exists to support an endosymbiotic origin for plastids, with the original endosymbiont being a photosynthetic cyanobacterium (Sato, 2006; Stiller, 2014). Two things happened during the ensuing 1.6 billion years of evolution: (1) approximately 90% of the plastid genome was transferred to the nucleus, and (2) the proto-chloroplast radiated and evolved into the other plastid types (Keeling, 2010). Secondary and tertiary endosymbiotic events and plastid loss complicate this simple picture, but the plastid family has a common origin. Thus, all plastids share the same basic characters of a double-membrane envelope; a separate and third internal membrane system of greater (chromoplast and chloroplast) or lesser (proplastid and amyloplast) complexity; a complete prokaryotic-like genetic machinery consisting of organellar DNA, transcription factors and ribosomes; and division by fission (again, very prokaryotic-like) (Miya-gishima and Kuroiwa, 2006). Unlike mitochondria, which were also derived endosymbiotically (Gray *et al.*, 1999), plastids did not surrender the anabolic abilities of their free-living ancestors. In fact, the power to manufacture all the biomolecules needed to support every metabolic and developmental pathway has enabled plants to use plastids as the central organelle for anabolism, catabolism, energy regulation, and environmental sensing.

Plastids of the Viridiplantae

Proplastid

Plants have egg cells, much like animals, and the egg cell is the sole source of organelles for the zygote that leads, eventually, to an adult plant. The plastids found in the egg are called ‘proplastids’ and are the progenitors of all the other plastids (regardless of type) found in the mature plant (Wise, 2006). Subsequent mitosis and the generation of new tissues in plants take place in zones at the tips of shoots and roots called

meristems. Meristematic plant cells also contain proplastids. Most plants continue to grow throughout their entire life to support shoot and root expansion. Therefore, they may have hundreds to thousands of meristems at any given time, and thus a large supply of proplastids.

Unlike the other plastid types, proplastids as a group are defined by their appearance and location, and not by any specific metabolic function. Characteristically, they are small, relatively nondifferentiated with a few internal membranes and only found in young, undifferentiated cells (Figure 2(a)).

Etioplast

Etioplasts develop in complete darkness and are a transitional stage between the proplastid and the chloroplast during the process of greening (Figure 1; Willows, 2006). The reverse process – degreening (chloroplast to etioplast) – is also possible as evidenced by the pale color that results under any light barrier laid on a green lawn (board, tarp, garden hose, etc). In this process, the green grass undergoes chlorosis (the controlled, enzymatic loss of chlorophyll) and degreens upon the imposition of darkness. Removing the obstruction allows the greening process to resume. Thus the etioplast-to-chloroplast-to-etoplast transition is quite dynamic and under strict genetic control (Zhong *et al.*, 2014).

Etioplast ultrastructure is dominated by the prolamellar body (PLB), a large, crystalline lattice of membranes (Figure 2(b); Gunning, 2001). While the exact function of the PLB remains obscure, it probably represents a ‘holding pattern’ for the large amount of membrane and protein that will ultimately be utilized in formation of the thylakoid system (see chloroplast, below). Interestingly, PLBs only form in dark-grown cells of the leaves and stems, tissues that under normal conditions will eventually be exposed to light. They never form in root cells. The plant growth regulator gibberellic acid (GA) is synthesized in the etioplast (Solymosi *et al.*, 2004). Because GA helps direct many early developmental processes, such as those in an expanding and greening leaf, the etioplast probably contributes directly to the light-to-dark transition.

Elaioplast

Lipid synthesis in animal cells is localized to the smooth endoplasmic reticulum (SER). However, SER is rarely seen in plant cells because most plant lipids are made in the proplastid, chloroplast, or elaioplast (Dörmann, 2006; Hernandez-Pinzon *et al.*, 1999; Bates *et al.*, 2013). Elaioplasts (Figure 2(c)) are plastids that specialize in oil synthesis and storage and are found primarily in the layer of cells in the anther that surrounds developing pollen grains (celled the tapetum or tapetal layer) (Suzuki *et al.*, 2013). After meiosis and just prior to pollen release, the tapetal layer degrades and

Figure 1 Plastids share a common progenitor and can be interconverted from one form to another. In the anther, proplastids develop into elaioplasts, oil-producing plastids. In the root, some amyloplasts accumulate starch for long-term storage while the amyloplasts in the root cap are involved in the mechanics of gravisensing. Proplastids in stems and shoots develop into etioplasts in the dark, but chloroplasts differentiate directly from proplastids if development takes place in the light. Chloroplasts perform a variety of important physiological and metabolic functions. Chloroplasts in immature tomato and peppers, for example, differentiate into brightly colored chromoplasts during ripening. Resource recovery from senescing leaves is tightly regulated as chloroplasts are converted into gerontoplasts, which are ultimately discarded with the abscised leaf.

releases the elaioplasts which contribute their oils to the exine, the outer-most, waterproof pollen wall. Oil synthesis in seeds is a more complicated process that utilizes plastids (fatty acid synthesis), the ER (lipid assembly and maturation) and special oil bodies (storage) and the trafficking of precursors and products between and among the various compartments (Bates *et al.*, 2013). Plant seed oils provide a significant supply of calories for the world's population.

Amyloplast

Starch is a macropolymer of several thousand repeating glucose units, and cannot be synthesized by animals. All starch synthesis in plants occurs inside a plastid and large starch granules can be found in proplastids, chloroplasts, and amyloplasts. Chloroplasts make short-term transitory starch with the entire pool being synthesized during the day and degraded

and exported at night. Proplastids and, in particular, amyloplasts make long-term storage starch that may persist for weeks, months or even years. Stored plant starches, like oils (see above), represent a major contribution to human dietary needs.

While most plastid types can contain starch, amyloplasts are unique because of, and named after, the copious amounts of starch they synthesize in the form of large grains (Figure 2(d)). In another example of plastid versatility, amyloplasts play two uniquely different roles in plant physiology. The function of amyloplasts in starch storage has already been noted. A second, separate function is in gravisensing (Palmieri and Kiss, 2006). Starch is heavy and starch-filled amyloplasts sediment on a minute time scale, even within plant cells. Amyloplasts in special tissues in the stem (the endodermis) and the root (the columella of the root cap) perform a mechanical, not a metabolic, function as they sink to the

bottom of the cell and signal an upper/lower cell polarity that initiates a gravitropic growth response (Toyota *et al.*, 2013). Shoots exhibit negative gravitropism and grow away from the signal, or up, while roots exhibit positive gravitropism and grow towards the signal, down.

Chromoplast

Chromoplasts contribute the bright red, orange, and yellow colors to many fruits, colors needed to attract and conscript animals to act as seed dispersers (Bouvier and Camara, 2006).

They originate as chloroplasts and the chloroplast-to-chromoplast transition (Figure 1) is tightly coordinated with the complex process of fruit ripening (Bramley, 2002; Kilcrease *et al.*, 2013).

The colors of chromoplasts come from large accumulations of carotenoid pigments of which there are two types, carotenes (carbon and hydrogen only) and xanthophylls (C, H plus oxygen) (Cuttriss *et al.*, 2006). In addition to functioning as animal visual attractants, the carotenoids are also precursors for Vitamin A biosynthesis in animals, thus rewarding seed dispersers with an essential nutrient. During the chloroplast-to-chromoplast transition, the chlorophyll-containing thylakoid membranes of the chloroplast are degraded and replaced with outsized pigment-protein droplets (Figure 2(e)). The protein fibrillin, which has many other functions in plant cells (Heinrich and Grossman, 2013), helps maintain the structure of the large hydrophobic accumulations (Singh and McNellis, 2011).

Gerontoplast

Leaf cells contain thousands of individual chloroplasts, and each chloroplast is rich in the proteins needed for photosynthesis. Autumnal senescence ('fall colors') is a genetically programmed, step-by-step dismantling of the chloroplast with the sole purpose of recovering that leaf protein. Cell walls and chloroplast lipids, including the lipid chlorophyll, are not recovered. As senescence proceeds, thylakoid membranes are degraded, lipids and pigments form large droplets and the chloroplast is slowly converted to a 'gerontoplast' (Figure 2(f); Harris and Arnott, 1973). Gerontoplasts have few internal membranes and large lipid/pigment droplets called plastoglobuli. They represent the catabolic end product of resource recovery (Krupinska, 2006).

Autumnal senescence has four steps. (1) Carbon accumulation: Warm autumn days promote photosynthesis and the production of leaf starch. Cool autumn nights, however, inhibit the translocation of that starch (as low-molecular-weight carbon compounds) out of the leaf via the phloem of the vasculature system. Therefore, in the fall leaves of deciduous species become overloaded with starch and photosynthesis is inhibited. (2) Carbon diversion (color formation): In order to remove the starch and restore the basal level of photosynthesis needed to support step 3, leaf carbon is converted into pig-

ments such as orange/red carotenoids. These lipids accumulate in large, hydrophobic droplets within the plastid. (3) Protein removal and chlorophyll detoxification: All chlorophyll in a chloroplast is safely bound to pigment-binding proteins, in order to direct and control energy absorption and processing. During senescence proteases and lipases degrade the thylakoid membrane, releasing chlorophyll. Free chlorophyll is a very potent photodynamic toxin and must be detoxified by chlorophyllases, with the resulting catabolites being shuttled into the vacuole. In short, the green pigments are removed and the thylakoid lipids join the carotenoid in the lipid droplets. (4) Leaf abscission: When all the proteins has been catabolised and translocated out of the leaf, a layer of cork cells forms where the leaf petiole attaches to the stem. Cork cells are weak, and they are waterproof. Eventually, the layer breaks, the leaf falls to the ground, and every hole that might have been left behind is plugged with a little bit of cork.

Chloroplast

Chloroplast structure

The typical C3 chloroplast is a round, plano-convex organelle approximately 5–10 μm in diameter (see below for definition of the C3 photosynthetic pathway). It has a double-membrane envelope and a third, internal system of membranes, thylakoids, that is suspended in a protein-rich fluid, the stroma (Figure 2(g)). In a functional chloroplast, thylakoids form a closed, flattened volume, with the stroma to the outside and the lumen to the inside. Thylakoids are of two varieties. Granal thylakoids are appressed together in stacks called grana; an individual granum may contain 2–30 or more thylakoids. Stromal thylakoids are unappressed and span the stroma to interconnect grana (Figure 2(h)). The three-dimensional architecture of this complicated membrane system appears to have a quasihelical structure (Mustárdy *et al.*, 2008), although due to the dynamic nature of the system, and technical difficulties, some refinement of that model may yet result (Daum and Kühlbrandt, 2011). Plants utilizing the C4 photosynthetic pathway have dimorphic chloroplasts (see below).

Chloroplast functions

Because chloroplasts have a constant supply of reduced carbon, NADPH, and ATP and originated from free-living

Figure 2 Common plastid types. Scale bar=5 μm in all images. (a) Proplastid (*Ipomea batatas* – sweet potato – root). This proplastid from a has only a few, disorganized internal membranes. It would probably have differentiated into an amyloplast, given it's location in the root. Scale bar=1 μm . (b) Etioplast (*Avena sativa* – oat – leaf). Large prolamellar bodies (PLB) occupy the majority of the etioplast interior. Scale bar=2 μm . (c) Elaioplast (*Brassica napus* – oilseed rape – tapetum). The plastid interior is almost completely filled with light-colored oil droplets. This oil reserve will be used to waterproof the developing pollen grains prior to their release. Scale bar=2 μm . (d) Amyloplast (*Vicia faba* – mung bean – root tip). An amyloplast from mung bean (*Vicia faba*) root tip. This gravisensing amyloplast has copious amounts of starch (S). Portion of the nucleus (N) is in the top right, and ER tubules lie between the amyloplast and cell wall (CW). The gravitational vector in this image is indicated by the arrow. Scale bar=2 μm . (e) Chromoplast (*Solanum esculentum* – tomato – fruit). Few internal membranes remain in this chromoplast and large pigment/protein/lipid droplets (PG) fill the chromoplast interior. Scale bar=2 μm . (f) Gerontoplast (*Nicotiana tabacum* – tobacco – leaf). A gerontoplast from tobacco has little starch (S), few internal membranes and numerous plastoglobuli (PG). Scale bar=2 μm . (g) C3 chloroplast (*Spinacia oleracea* – spinach – leaf). This typical C3 chloroplast is from a spinach (*Spinacia oleracea*) leaf. It contains grana (G), one starch grain (S) and an area of stroma (St). Two mitochondria (M) can be seen in the lower right of image, below the cell wall (CW). Scale bar=5 μm . (h) Grana (*Spinacia oleracea* – spinach – leaf). Several individual grana (G) are interconnected via stromal thylakoids (ST). Plastoglobuli (PG) can be seen in the lower right corner. The two membranes of the chloroplast envelope are indicated between the two arrowheads. T=tonoplast (vacuole membrane). Scale bar=1 μm . (i) Granal and agranal C4 chloroplasts (*Zea mays* – maize – leaf). Portions of two cells are shown, a bundle sheath cell to the left contains an agranal chloroplast and a mesophyll cell to the right contains a granal chloroplast. A cell wall (CW) separates the two cells. Scale bar=5 μm . IAS, intercellular air space, M=mitochondrion, V=vacuole.

prokaryotic endosymbionts, they have evolved over time to be capable of performing a large array of anabolic functions in a plant cell. Some of those functions are given here.

Photosynthesis and starch synthesis

Chloroplasts use photosynthesis to manufacture low-molecular-weight, reduced carbon compounds, commonly called sugars. In brief, photosynthesis can be divided into two distinct sets of reactions (Hoober, 2006). The 'light-dependent reactions' harvest light energy and use that energy to transport electrons through an electron transport chain embedded in the thylakoid membrane. Chlorophyll is the primary photosynthetic pigment; hence, thylakoid membranes are deep green in color. The light-dependent reactions synthesise ATP and the reductant NADPH. Subsequently, the 'light-independent reactions' use that NADPH and ATP to reduce and phosphorylate oxidized atmospheric carbon to the level of a sugar phosphate.

The 'light-dependent reactions' have an electron transport chain consisting of two photosystems, PSII and PSI, connected by a series of redox-active lipids, proteins, and metal cofactors (Figure 3). Each photosystem has as its core a reaction center (RC) surrounded by antenna complexes containing 300–400 molecules of chlorophyll, several molecules of carotenoid, and numerous pigment-binding proteins. When a chlorophyll molecule absorbs the energy of a photon, that energy is transferred from chlorophyll to chlorophyll through the antenna complex until it is ultimately absorbed by the reaction centers of PSII (P680) or PSI (P700). Note that the antenna does not contain a redox chain – electrons are not being transported, only the absorbed energy. The RC is made of two special chlorophyll molecules that are capable of performing a 'photoact,' i.e. undergoing oxidation and reducing the electron transport chain. The electron ejected from P680 of PSII ultimately reduces a molecule of the lipid plastoquinone (PQ). When doubly reduced with two electrons and two protons, the resulting PQH₂ debinds from PSII, diffuses to and reduces the

cytochrome *b₆/f* complex (Cyt *b₆/f*). The oxidized P680 becomes re-reduced by drawing an electron out of the adjacent water splitting apparatus (WSA). When four electrons have been extracted by PSII (requiring the absorbed energy of four photons), four protons and one molecule of O₂ are released by the WSA (Figure 3 is drawn based on a stoichiometry of two electrons per one NADPH). The absorption of a photon by a PSI antenna chlorophyll drives a second photoact, ultimately reducing NADP⁺ to NADPH. Oxidized PSI extracts an electron from plastocyanin (PC), which is re-reduced by electrons from the cytochrome *b₆/f* complex. Thus, whole-chain photosynthetic electron transport uses the energy of sunlight to oxidize low energy water, and reduce high-energy NADPH.

ATP is also synthesized by the light-dependent reactions, via chemiosmosis. The transthylakoid pH gradient needed to drive chemiosmosis is generated by two mechanisms: (1) the oxidation of one molecule of water produces two free protons, and (2) proton pumping via the PQ pool. When electrons coming from PSII reduce plastoquinone, the two protons needed to complete the reaction come from the stromal side of the thylakoid membrane. Then, when the resultant PQH₂ is oxidized, two electrons enter the cytochrome *b₆/f* complex the two protons are delivered to the thylakoid lumen. In this way, photosynthetic electron transport generates protons in the lumen and pumps protons across the thylakoid membrane, lowering the luminal pH from roughly 7 in the dark to approximately 5 in the light. This substantial pH gradient is used to synthesise ATP in the light.

The light-independent reactions are located in the stroma and use the ATP and NADPH produced by the thylakoid membrane to reduce and phosphorylate atmospheric CO₂ to the level of glyceraldehyde-3-phosphate (G3P). Photosynthesis does not make glucose as an end product. It makes G3P. The resulting triose phosphate can be exported from the chloroplast and be translocated to all parts of the plant. Alternatively, if photosynthesis is running faster than translocation,

Figure 3 Photosynthetic electron transport. See text for explanation.

the G3P is temporarily stored within the chloroplast as starch. Starch levels are typically high at the end of the light period, and low at pre-dawn. 'Photosynthesis' literally means to use light to fuel an anabolic process. In that regard, photosynthesis makes carbohydrates, amino acids, proteins, lipids, and nucleic acids – every reduced-carbon molecule in the plant.

Nitrogen assimilation, sulfur assimilation, amino acid synthesis, and protein synthesis

Nitrogen and sulfur are 2 of the 20 essential elements plants need for growth and development. Both are rather scarce in the environment, at least in bioavailable forms. While different pathways are responsible for their uptake (and will not be discussed here), once in the plant both elements must be assimilated into safe, transportable, and usable forms such as amino acids (Lancien *et al.*, 2006; Pilon-Smits and Pilon, 2006).

As a class of chemical compounds, there are about 500 amino acids, of which only 20 are used to make proteins. These are the so-called proteinogenic (or proteinaceous) amino acids. Humans can only make 11 of the 20 proteinogenic amino acids. In contrast, plants can synthesize all 20 proteinogenic amino acids and plastids are the site for the synthesis for the nine essential amino acids (Lancien *et al.*, 2006). Lacking plastids, humans must acquire these nine 'essential' amino acids via their diet, by eating plants, or other animals that feed on plants. Glyphosate (Roundup®) is a potent inhibitor of a key plastid enzyme in the aromatic amino acid pathway (phenylalanine, tyrosine, and tryptophan) and, thus, a powerful and specific herbicide (Amrhein *et al.*, 1980). Synthesis of the branched chain amino acids (isoleucine, leucine, and valine) is also plastid localized and the subject of specific herbicide inhibition (Lancien *et al.*, 2006).

Lipid and pigment synthesis

Plastids, in one form or another, synthesize chlorophylls (Willows, 2006), carotenoids (Cuttriss *et al.*, 2006), fatty acids, phospholipids, sulfolipids and galctolipids (Dörmann, 2006), tocopherols (Lushchak and Semchuk, 2012), and quinone lipids (Jones *et al.*, 2013; Kim *et al.*, 2008). Plant cells only rarely possess smooth endoplasmic reticulum, the site of most lipid synthesis in animals.

Chloroplast variants

The dimorphic chloroplasts of C4 photosynthesis

The photosynthetic pathway described above results in the generation of a three-carbon compound, glyceraldehyde-3-phosphate. Hence, plants that use this pathway are called C3 plants. Other plants, most notably grasses such as maize and sugar cane, produce a four-carbon acid as the first stable product of photosynthesis. That form of photosynthesis is called the C4 pathway.

C4 plants differ from C3 plants on biochemical, physiological, anatomical, and ultrastructural bases (Sage, 2004). In C4 photosynthesis, carbon dioxide is initially fixed in chloroplasts in the mesophyll cells of the leaf. Mesophyll cell chloroplasts contain grana stacks, and are termed 'granal' (Figure 2(i), right side). The four-carbon compound resulting from the initial fixation, is transported to the bundle sheath

cells, where it is decarboxylated to a three-carbon molecule and CO₂. The released CO₂ is then fixed again in the bundle sheath chloroplast which lacks grana ('agranal') (Figure 2(i), left side). The different ultrastructures arise because the enzyme responsible for the secondary fixation in the bundle sheath chloroplast (ribulose-bis-phosphate carboxylase/oxygenase or RubisCO) is inhibited in the presence of oxygen. Unlike C3 chloroplasts and C4 mesophyll cell chloroplasts, the C4 agranal bundle sheath chloroplasts are non-oxygenic, thus the O₂ inhibition of RubisCO is alleviated.

Guard cell chloroplasts

Stomata (pl., stoma=sing.) are minute, adjustable pores on the leaf surface that allow for CO₂, H₂O, and O₂ gas exchange between the leaf and the atmosphere. A pair of epidermal cells called guard cells inflate with water, bend and open the stomatal pore. Subsequent loss of water causes the guard cells to deflate, and close the pore. In most plants stomata are closed at night (when photosynthesis cannot operate) and open during the day and the signals to open and close come from environmental cues and an internal circadian clock. The energy to drive the opening and closing comes from guard cell chloroplasts (GCC). The mechanism is based on the movement of osmolytes that influence cell water potential and osmotically driven water movements.

GCC are, in all respects, the same as C3 chloroplasts. They contain thylakoids, grana, chlorophyll, and all the components needed to perform both the light-dependent and the light-independent reactions of photosynthesis (Outlaw *et al.*, 1981; Fitzsimons and Weyers, 1983). They fix carbon and make starch (Gotow *et al.*, 1988). What sets GCCs apart from other chloroplasts is that they contribute nothing to the carbon economy of the leaf. GCCs function solely to provide the energy and osmotica needed to drive stomatal opening and closing.

GCC are an example of the evolutionary flexibility of plastids. Plants evolved from green algal ancestors and began land colonization during the Ordovician period (approximately 470 million years ago). One of the many adaptations needed for a terrestrial life was a waxy, water impervious outer cuticle which drove the need for stomatal openings in that cuticle. As guard cells evolved, plastids were enlisted to serve as the power plant for stomatal functioning. They are sensitive to light (and light is a major signal for stomatal opening) and can generate the low-molecular-weight osmolytes needed to support osmotically driven stomatal opening and closing.

Sun versus shade chloroplasts

Chloroplast development is light-dependent (Apel *et al.*, 1983) and different ultrastructures and physiologies can result as a consequence of the light environment during development (Lichtenthaler *et al.*, 1981). Because light is limiting in the shade, chloroplasts in leaves that develop in the interior of a tree canopy develop to favor the light-dependent reactions over the light-independent reactions. Shade-type chloroplasts are optimized for light capture with larger grana, more thylakoids per granum and more chlorophyll per antenna complex. Stromal volume is concomitantly reduced. Sun-type chloroplasts, which develop at the exterior of the canopy where light is not limiting, have smaller grana, less chlorophyll (reduced

capacity for the light-dependent reactions) and more stromal volume (increased capacity for the light-independent reactions). Both chloroplast types can be found on the same plant, thus these two different developmental outcomes are driven solely by the light environment experienced during leaf expansion.

Accurate and efficient trafficking of lipids and proteins is fundamental for cell growth, communication, and response to environmental conditions. Secretory and membrane proteins represent up to a third of the proteome in the model eukaryote, *Saccharomyces cerevisiae*. These proteins are synthesized and matured in the endoplasmic reticulum (ER), then subsequently captured into vesicles fashioned by COPII coat proteins in the first step of their journey to their final destination.

The COPII Coat

The formation of ER-derived COPII vesicles results from the sequential recruitment of the minimal machinery composed of five individual coat proteins: Sar1, Sec23, Sec24, Sec13, and Sec31 (Figure 1; Barlowe *et al.*, 1994). These components are sufficient to generate vesicles from synthetic membranes in the absence of other proteins (Matsuoka *et al.*, 1998), but in cells various interacting partners (e.g., Sec12 and Sec16) serve to regulate this process. Activation of the small G protein, Sar1, by the ER membrane localized guanine nucleotide exchange factor (GEF), Sec12, induces a structural change upon exchange of GDP for GTP that exposes an amphipathic α -helix that inserts into the ER membrane (Yoshihisa *et al.*, 1993).

Sar1.GTP initiates membrane curvature (Bielli *et al.*, 2005; Lee *et al.*, 2005) and recruits the coat inner layer (Antonny *et al.*, 2001), composed of the heterodimeric complex of Sec23 and Sec24, through direct interaction with Sec23 (Bi *et al.*, 2002). Finally, the heterotetrameric complex of Sec13 and Sec31, referred as the outer coat layer, is recruited via a complex set of interactions with the ‘prebudding’ complex Sar1/Sec23/Sec24 (Antonny *et al.*, 2001; Bi *et al.*, 2007). Purified Sec13/Sec31 is capable of forming spherical assemblies that resemble the diameter of COPII vesicles (Stagg *et al.*, 2006), suggesting that the outer coat contributes to membrane deformation and establishes the geometry of the vesicle.

Cargo Capture during Vesicle Formation

Efficient incorporation of cargo proteins into COPII vesicles is triggered by the cytosolic presentation of protein-based signals, referred as sorting signals or export motifs, that bind to discrete cargo-recognition sites on the surface of Sec24 (Miller *et al.*, 2003; Mossessova *et al.*, 2003). Secretory proteins that cannot bind directly to Sec24, because of lack of signals or topology constraints, make indirect contact with the COPII coat by interacting with membrane proteins that themselves present a binding motif for Sec24 (Dancourt and Barlowe,

Figure 1 Hierarchical assembly of the COPII coat. Vesicle formation proceeds via defined steps: (i) The G-protein, Sar1, is locally activated by its GEF, Sec12, which drives membrane insertion of an amphipathic α -helix that initiates membrane curvature; (ii) GTP-loaded Sar1 recruits the cargo-binding adapter complex, Sec23/Sec24, which binds to specific sorting signals on cargo proteins (gray/brown proteins) or cargo receptors (blue proteins); (iii) this 'prebudding complex' recruits the outer coat layer, Sec13/Sec31, which polymerizes into a spherical structure thereby driving membrane curvature and completing vesicle formation.

2010). This class of proteins, known as receptor proteins, includes receptors such as yeast Erv29 (Belden and Barlowe, 2001) and mammalian ERGIC-53 (Appenzeller *et al.*, 1999) that bind to soluble luminal cargoes. Some classes of membrane proteins, like GPI-anchored proteins, are embedded in the bilayer by a luminal lipid anchor and thus are topologically unable to bind directly to the COPII coat. Such cargo proteins must also employ receptors, in the case of GPI-anchored proteins, the p24 family of proteins mediate efficient ER export (Muniz *et al.*, 2000). Additional cargo receptors, like Erv26 and Erv14 (Dancourt and Barlowe, 2009; Herzig *et al.*, 2012; Powers and Barlowe, 2002), mediate efficient export of transmembrane proteins even though such cargoes can potentially interact directly with Sec24. Recent work on Erv14 suggests that this receptor serves to strengthen the interaction of a cargo with Sec24 by providing a second signal that must be recognized simultaneously with a cargo-borne signal (Pagant *et al.*, 2015).

The relatively small subset of ER export motifs defined so far fail to conform to a canonical ER export signal, and instead range in character from simple 2–3 amino acid motifs to larger folded epitopes. Moreover, four independent cargo-binding sites on the surfaces of the yeast and mammalian Sec24 isoforms have been structurally and functionally characterized: the so-called yeast A-site binds an N-P-F motif on Sed5 (Miller *et al.*, 2005; Mossessova *et al.*, 2003); the yeast and mammalian B-site is responsible for the packaging of numerous proteins and can recognize different motifs, most notably simple acidic-based signals; the conserved C-site binds a folded epitope formed by the longin domain of the SNARE, Sec22 (Mancias and Goldberg, 2007; Miller *et al.*, 2003); an additional final site on mammalian Sec24 recognizes the mammalian SNARE proteins, membrin and syntaxin5 (Mancias

and Goldberg, 2008). The repertoire of binding site-export motif pairs is further expanded by the existence of multiple Sec24 isoforms (three in yeast and four in mammals), that each possess distinct cargo-binding specificities. As an example, the I-X-M motif of membrin and syntaxin5 binds a surface groove on the mammalian SEC24C and SEC24D isoforms that is occluded in the structure of the SEC24A and SEC24B proteins (Mancias and Goldberg, 2008). Similarly, the packaging of PCSK9 and Vangl2 is specifically mediated by SEC24A and SEC24B (Chen *et al.*, 2013; Merte *et al.*, 2010), whereas the transporters of the SCL6 family favor the SEC24C or SEC24D isoforms (Sucic *et al.*, 2011, 2013). Conversely, any of the four SEC24 isoforms are competent to promote ER export of ERGIC-53 (Merte *et al.*, 2010), a cargo receptor for coagulation factors. This level of specificity might have evolved to finely regulate the deployment of key players of various developmental processes.

Regulation of COPII Biogenesis: The GTPase Cycle

The GTPase cycle of Sar1 is the central regulator of COPII trafficking since it influences multiple steps of vesicle formation. Association of Sar1.GTP with the ER membrane occurs via an N-terminal amphipathic α helix that may initiate curvature on the membrane and/or alter the physical properties of the bilayer to make it more susceptible to deformation (Lee *et al.*, 2005; Loftus *et al.*, 2012; Settles *et al.*, 2010). Sar1.GTP also stimulates the local recruitment of the other COPII proteins at the ER exit sites (ERES). Moreover, vesicle release from the membrane also requires both the N-terminal helix and GTPase activity of Sar1 (Bielli *et al.*, 2005; Lee *et al.*, 2005). Finally, GTP hydrolysis on Sar1 is thought to

destabilize membrane association of the other coat proteins and thereby contribute to vesicle uncoating that precedes fusion with the cis-Golgi acceptor membrane (Antonny *et al.*, 2001; Barlowe *et al.*, 1994). Given these multiple roles of the GTPase cycle of Sar1 in COPII vesicles biogenesis, it is not surprising that a suite of effectors contributes to quantitative and local regulation.

Like most G-proteins, Sar1 possesses very low intrinsic GTPase activity, but basal hydrolysis is enhanced during polymerization of the coat; Sec23 is the GTPase-activating protein (GAP) for Sar1, stimulating GTP hydrolysis by inserting a catalytic arginine residue into the GTP-binding pocket of Sar1 (Bi *et al.*, 2002). Furthermore, binding of an unstructured loop of Sec31 to the Sec23–Sar1 interface repositions this arginine residue, resulting in a 10-fold increase in GTPase activity (Bi *et al.*, 2007). This results in a somewhat counterintuitive scenario whereby coat assembly, and in particular coupling between the inner and outer coat layers, should drive coat depolymerization. Clearly, additional layers of regulation must spatially and temporarily stabilize the coat to complete vesicle biogenesis.

One mechanism that contributes to modulation of the Sar1–GTP cycle is its GEF, Sec12, which catalyzes GTP loading on Sar1 with a turnover 10-fold higher than the coat-stimulated GAP activity (Futai *et al.*, 2004; Sato and Nakano, 2005). Since Sec12 is not packaged into COPII vesicles, its presence in the ER membrane could drive local COPII assembly sufficient for vesicle formation, then its absence from vesicles would shift the balance toward the Sec23-driven GAP activity and uncoating. Consistent with this model, Sec12 is concentrated at ERES through binding with Sec16 (discussed below) in the budding yeast, *Pichia pastoris* (Rossanese *et al.*, 1999; Soderholm *et al.*, 2004), and in mammalian cells (Montegna *et al.*, 2012). However, in *Saccharomyces cerevisiae*, Sec12 is dispersed across the entire ER, and ERES marked by COPII coat proteins are smaller and more numerous, raising questions about the distribution of Sec12 as a primary driver of ERES stability and organization (Rossanese *et al.*, 1999). Interestingly, mammalian cells show ERES recruitment of Sec12 independent of Sec16, but contingent on cTAGE5 (Saito *et al.*, 2014), an ER protein involved in transport of procollagen, a remarkably large cargo that requires carriers of much bigger size than canonical COPII vesicles (discussed further below). Together, the *in vitro* and *in vivo* data suggest that local GEF activity can counter Sar1 GTP hydrolysis, but that spatial restriction of this activity to discrete ERES is not absolutely required for secretion. Instead, ERES enrichment of Sec12 may be critical for packaging of ‘difficult’ cargoes that require larger structures and therefore prolonged coat association.

Multiple lines of evidence delineate a major role for the large ER membrane protein, Sec16, in promoting COPII vesicle biogenesis. However, its mechanism of action in this process is complex and remains to be fully understood. Purified Sec16 can bind *in vitro* to synthetic liposomes and in turn drive the stable recruitment of the COPII coat proteins through multiple interactions (Espenshade *et al.*, 1995; Gimeno *et al.*, 1996; Supek *et al.*, 2002). In *Pichia pastoris* and mammalian cells, Sec16 localizes at ERES with a lifetime higher than that observed for COPII coat proteins. Moreover, the observation that ERES formation is impaired in the absence of Sec16

strongly suggests a role in organization of the COPII coat at specific localizations on the ER membrane (Connerly *et al.*, 2005). Recent findings also indicate that the GTPase stimulatory effect of Sec31 can be attenuated by Sec16 (Kung *et al.*, 2012; Yorimitsu and Sato, 2012). Therefore, it remains unclear to what extent the capacity of Sec16 to maintain ERES structure results from its action in reducing Sar1 GTPase activity, from its binding with Sec12 or from its ability to stabilize coat polymerization by scaffolding the other COPII components.

Cellular Regulation of COPII Vesicle Biogenesis

Despite intricate knowledge of COPII coat structure and function *in vitro*, major questions remain about how the process of vesicle formation is regulated to satisfy specific cellular demands during development, differentiation or stress. These questions are now being explored using large-scale screens. Systematic knock-down analysis of human kinases and phosphatases identified 122 proteins that affect ER export, ERES formation, and/or the Golgi apparatus (Farhan *et al.*, 2010). Among the candidates identified, ERK2 impacted phosphorylation of Sec16 and depletion of this member of the Raf–MEK–ERK cascade led to a reduction in the number of ERES. In a separate study, overexpression of ERK7 negatively impacted ERES formation through the redistribution of Sec16 to the cytosol from ERES (Zacharogianni *et al.*, 2011). Taken together, these results place Sec16 as a major signal integrator, capable of modulating COPII vesicle formation sites in response to cellular conditions. Sec16 is also responsible for mediating changes in ERES number during increases in cargo load at the ER, although the signaling events that modulate these events are not known.

Proteome-wide analysis of posttranslational modifications have identified the COPII coat proteins as targets of phosphorylation, ubiquitylation, and acetylation, but how these changes affect COPII vesicle production and how they relate to specific cellular regulation remain largely unexplored. In a more targeted study, recombinant Akt, whose perturbation is linked to cancer and diabetes, directly phosphorylated mammalian SEC24, which resulted in decreased binding SEC23 (Sharpe *et al.*, 2011). These data suggest that one avenue for cellular signaling to regulate secretory flux is by preventing Sec24 integration into prebudding complexes. Sec23 and Sec24 are also phosphorylated by a CK1 kinase, Hrr25/CK1δ, although these phosphorylation events have been implicated in vesicle delivery rather than in more global regulation of secretory events (Lord *et al.*, 2011).

Additional layers of regulation likely come from a growing number of accessory proteins that interact with the various coat components but contribute to traffic in poorly understood ways. Such proteins include the Sec23- and Sec31-interacting protein p125 (Klinkenberg *et al.*, 2014; Ong *et al.*, 2010; Shimoi *et al.*, 2005), the Sec16-interactor TFG-1 (Witte *et al.*, 2011), and the Ca(2+)–binding protein ALG-2 (Helm *et al.*, 2014). ALG-2 binds specifically to SEC31 in a calcium-dependent manner and its depletion impairs the recruitment of the COPII outer coat at ERES. Moreover, addition of ALG-2 to *in vitro* budding reactions showed that ALG-2 significantly reduced the formation of COPII vesicles, and that its

inhibitory effect was calcium-dependent (la Cour *et al.*, 2013). The mechanistic effects of such accessory proteins and how they may also be points of cellular regulation remain to be more fully explored.

Regulation of Vesicle Size

COPII vesicles produced *in vitro* by the yeast minimal machinery (Sar1, Sec23/Sec24, Sec13/Sec31) range from 60 nm to 80 nm in diameter (Barlowe *et al.*, 1994). However, the secretion of unusually sizable cargoes, such as procollagen fibers and chylomicrons, requires the production of much larger carriers. Recent evidence from cryo-EM structures strongly suggests that the geometry of the outer Sec13/Sec31 complex contributes to shaping carriers from the ER membrane. Purified mammalian Sec13/Sec31 can self-assemble into spherical cages with cuboctahedral geometry, although larger and more irregularly shaped structures can also be observed, suggesting that the outer coat might be adaptable to different vesicle shapes (Noble *et al.*, 2013; Stagg *et al.*, 2006, 2008). Cage assembly in the prevailing cuboctahedral structure is driven by Sec31 oligomerization at two interfaces: tail-to-tail dimerization of two Sec31 molecules via their α -solenoid domains; and 4-fold interaction via N-terminal β -propeller domains (Fath *et al.*, 2007; Noble *et al.*, 2013). In support for a fundamental role of Sec31 in sculpting COPII carriers, monoubiquitylation of mammalian Sec31 induces the formation of distended COPII structures at ERES and is specifically essential for ER export of procollagen fibers (Jin *et al.*, 2012). Sec13 forms a partial β -propeller that inserts between the α -solenoid and β -propeller domains of Sec31, and is thought to provide rigidity to the cage. Deleting a flexible hinge region of yeast Sec31 that encompasses the Sec13 binding site complements the lethality associated with the absence of Sec13 in yeast (Copic *et al.*,

2012). Similarly, the essentiality of Sec13 could be rescued by inhibiting the ER export of GPI-anchored proteins, suggesting that cargo burden and/or ER membrane composition influence the cellular function of the outer coat.

The inner coat layer, composed of Sec23 and Sec24, has also been evoked to provide structural regulation that may determine vesicle shape and size. Cryo-EM analysis revealed that in the presence of Sec23/Sec24, Sec13/Sec31 assembly generates icosidodecahedral cages of ~ 100 nm in diameter (Stagg *et al.*, 2008). Furthermore, cryo-EM of the yeast COPII coat assembled on synthetic liposomes revealed long membrane tubules that were densely coated with oligomeric arrays of Sec23/Sec24 (Zanetti *et al.*, 2013). One emerging model is that the positioning of Sec23/Sec24 can influence the geometry of Sec13/Sec31 and thereby alter the architecture of the underlying membrane. In further support of a role for the inner coat in modulating vesicle size, vesicles produced *in vitro* with the yeast Sec24 isoform Sfb2/Lst1 are larger than the standard COPII vesicles (90 nm for Lst1 vs 60 nm for Sec24) (Shimoni *et al.*, 2000). Interestingly, Lst1 is required for traffic of Pma1 oligomers and GPI-anchored proteins, both of which associate with ceramide-rich lipids and may correspond to cargoes that require more spacious carriers (Lee *et al.*, 2002; Peng *et al.*, 2000; Roberg *et al.*, 1999). Together these data suggest that Sec24 isoforms might influence the diameter of the COPII vesicles and/or cages in response to the specific cargo with which they interact.

Sec23, the other inner coat protein, has been more directly implicated in the production of COPII carriers that transport large cargo proteins. Point mutations in conserved residues of human SEC23A have been linked with a craniofacial disorder in which bone abnormalities are thought to arise from defects in collagen secretion. The first mutation (F382L) linked with this disease changes a residue directly involved in the interaction between Sec23 and Sec31, and presumably leads to defective

Figure 2 Packaging of noncanonical cargo. Some cargoes, like procollagen and lipid particles, are too large to fit into a standard COPII vesicle, so the budding process must be altered in some way. Specific accessory proteins like TANGO1 and cTAGE5 are thought to specifically alter COPII coat assembly to create conditions that permit procollagen traffic. cTAGE5 binds Sec12 to initiate coat recruitment locally; TANGO1 binds procollagen in the lumen and may link it to these regions of Sec12 activity. One current model is that accessory proteins prevent recruitment of Sec13/Sec31 and thereby prolong the coat assembly phase prior to vesicle release.

Figure 3 Directionality of vesicle delivery. Once a vesicle has been released from the ER it must be delivered to the appropriate target membrane. This process is driven by sequential interactions of Sec23 with various tethering and fusion regulators. When GTP hydrolysis is complete and Sar1 has been released from the vesicle, the TRAPP component, Bet3, binds to Sec23. TRAPP initiates local activation of Ypt1/Rab1, which in turn recruits coiled-coil tethers like Uso1/p115. Phosphorylation of Sec23 drives TRAPP release, and may prime the vesicle for uncoating, which would expose the SNARE machinery that ultimately drives membrane mixing.

vesicle fission since extended ER cisternae and uncoated tubular projections were observed in patient-derived fibroblasts (Boyadjiev *et al.*, 2006). The precise mechanism by which these mutations affect vesicle production remains to be determined, since the loss of Sec31/Sec13 recruitment might impact the physical capacity for the coat to deform ER membrane but also impact GTPase activity on Sar1. A second disease-associated SEC23A variant (M702V) is specifically defective for collagen transport, since vesicle formation and traffic of most cargo proteins remained unaffected (Kim *et al.*, 2012). Unlike SEC23-F382L, SEC23-M702V does not diminish association with Sec31 but results in elevated SAR1B GTPase activity. In support of a model in which the SAR1B GTPase cycle is regulated to allow the transport of large secretory cargo, efficient packaging of large lipid particles known as chylomicrons also relies specifically on SAR1B activity (Jones *et al.*, 2003).

In addition to the coat itself, further accessory proteins may also contribute to generation of large COPII carriers (Figure 2). One such component is the metazoan ER membrane protein, TANGO1, which interacts with procollagen in the ER lumen and with Sec23/Sec24. Unlike canonical receptors that promote ER exit of luminal cargoes, TANGO1 itself is not incorporated into COPII vesicles (Saito *et al.*, 2009). It has been proposed that binding of these proteins to the inner coat might interfere with recruitment of Sec31 onto Sec23 and therefore restrain the GAP activity associated with the full coat and prevent premature vesicle scission. Moreover, the TANGO1-related protein, cTAGE5 (Saito *et al.*, 2011), associates with Sec12 at ERES, which could contribute additional coat stabilization (Saito *et al.*, 2014). Conversely, Sedlin, another binding partner of TANGO1, acts directly on Sar1 to reduce its conversion to Sar1-GTP (Venditti *et al.*, 2012). Sedlin is also implicated in procollagen trafficking since its deficiency leads to the collagen-related disease, spondyloepiphyseal dysplasia tarda (SED). Therefore, the exit of collagen from the ER may rely on both the activation of the Sar1 GTP cycle by cTAGE5–Sec12 and its inactivation by

TANGO1–Sedlin interactions. How those events are regulated to allow the formation of carriers efficient for the transport of procollagen or other large cargo proteins awaits further investigation. Furthermore, direct evidence addressing a role for GTPase regulation by TANGO1/cTAGE5 has not yet emerged, and additional potential roles in altering the geometry of the inner and outer COPII coat layers or altering membrane curvature have not been ruled out.

Vesicle Tethering

Following their release from ER membranes, COPII vesicles must target to and fuse with Golgi acceptor membranes (Figure 3). In mammalian cells, ER-derived vesicles also undergo homotypic fusion, which likely generates the ER–Golgi Intermediate Compartment (ERGIC), an intermediary sorting station that is also marked with COPI coat proteins. ERGIC membranes undergo long-distance transport to the Golgi proper. The mechanisms of tethering and fusion of ER-derived vesicles are broadly conserved from yeast to mammals, using much of the same machinery. Initial tethering of COPII vesicles seems to involve interaction between Sec23 and the transport protein particle I (TRAPP) complex, which functions as a GEF for the Rab GTPase, Ypt1 (Rab1 in mammals) (Lord *et al.*, 2011). TRAPP is composed of six subunits (Bet3, Bet5, Trs20, Trs23, Trs31, and Trs33) that assemble onto the surface of the COPII vesicles via direct interaction between Bet3 and Sec23. GTP loading on Ypt1/Rab1 recruits the activated Rab1 to the vesicle where it in turn drives recruitment of the coiled-coil tethering protein Uso1 (p115 in mammals) (Cao *et al.*, 1998; Seog *et al.*, 1994a). Structural analysis shows that the amino-terminal domain of p115 forms a dimer between two globular regions that contain Armadillo-like α -helical repeats, termed tether repeats (TRs), which are also found in other tethering factors (Seog *et al.*, 1994b; Yamakawa *et al.*, 1996). The extended coiled-coil structures of both p115 and Uso1 yield an average length of ~ 154 nm, which may be

required for the capture of vesicles at a significant distance away from the Golgi. In addition, the coiled-coil regions of p115/Uso1 can undergo local bending, which may facilitate multidirectional collection of vesicles and/or may indicate conformational change that would physically bring the vesicles close to the acceptor membranes.

Additional cis-Golgi localized proteins, GRASP65 and GM130, are also implicated *in vitro* to contribute to COPII vesicle tethering (Alvarez *et al.*, 2001; Behnia *et al.*, 2007; Nakamura *et al.*, 1995; Seemann *et al.*, 2000), although since their respective yeast orthologs, Grh1 and Bug1, are not essential for cell viability their importance in secretion remains to be fully determined (Levi *et al.*, 2010). Nevertheless, the observation that these proteins physically interact with Uso1 and that their respective deletions display negative genetic interactions with thermosensitive alleles of both Ypt1 and Uso1 suggests that they participate in tethering events perhaps redundantly with the Ypt1/Uso1 pathway (Behnia *et al.*, 2007). Indeed, these tethers connect directly to the COPII coat, binding to the Sec23/Sec24 complex independently of Ypt1. Tethering events that mediate Golgi delivery seem to be coordinated by the kinase, Hrr25/CK1 δ , which phosphorylates Sec23 and triggers release of TRAPPI (Lord *et al.*, 2011). These phosphorylation events may also destabilize the coat to permit local uncoating immediately adjacent to the acceptor membrane, an event that is required for exposure of the vesicle-borne fusion machinery.

Vesicle Fusion

Subsequent to vesicle tethering, the membranes of the acceptor compartment and vesicle must undergo fusion. This process is mediated by type II membrane proteins called SNAREs that share a conserved domain defined as the SNARE motif. SNAREs embedded in the vesicle membrane specifically interact with those located in the acceptor membranes to form 'trans' complexes that bring the opposing lipid bilayers in close proximity, which catalyzes their mixing. SNAREs are sub-categorized as Q-SNAREs or R-SNAREs based on the presence of conserved glutamine or arginine residues within the SNARE motifs. Membrane fusion generally requires the zipping of three Q-SNAREs (Qa, Qb, and Qc) and one R-SNARE. Vesicle fusion can be reconstituted with synthetic proteoliposomes using Sed5 as the Qa-SNARE, Bos1 as the Qb-SNARE, Bet1 as the Qc-SNARE, and Sec22 as the R-SNARE and *in vivo* studies also implicate this set of SNAREs in ER–Golgi traffic (McNew *et al.*, 2000). This process is also under the control of the Sec/Munc protein family member, Sly1, that binds to Sed5 to increase the fidelity of assembly between Sed5, Bos1, Bet1, and Sec22 relative to noncognate SNARE complexes (Cao and Barlowe, 2000). Once fusion is completed, the SNAREs remain associated in a cis-SNARE complex at the target membrane. This cis-SNARE complex is disassembled by SNAP/Sec17 and the AAA+ ATPase NSF/Sec18 in an ATP-dependent manner to allow the SNAREs to proceed in new rounds of membrane fusion.

Conclusions

In vitro reconstitution and yeast genetics have been instrumental in defining the essential actors involved in COPII

vesicle biogenesis. The further biochemical characterization of this minimal machinery and of various binding partners allowed the functional assignments of these key players to the different steps involved in vesicle formation, cargo protein recruitment, vesicle tethering and fusion. Forthcoming challenges include a better understanding of the molecular determinants that regulate these processes during development and various environmental conditions as well as the strategies employed to accommodate the transport of the vast diversity presented by the entire complement of eukaryotic secretory proteins.

N-Linked Glycans (N-Glycans)

P Stanley, Albert Einstein College Medicine, New York, NY, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Glycan A group of sugars synthesized by the sequential action of glycosyltransferases that link sugars to each other to form a linear or branched structure termed a glycan.

Glycosidase An enzyme that hydrolyzes the chemical bond between two sugar residues. There are exo- and endo-glycosidases.

Glycosylation The transfer of a sugar or glycan to protein or lipid to make a glycoprotein or glycolipid.

Glycosyltransferase Enzyme that catalyzes the transfer of the sugar from a nucleotide sugar to a protein or lipid, or to another sugar, in a specific linkage.

N-linked glycan Specific type of glycan linked to asparagine (Asn, N) in the sequence Asn-X-Ser/Thr where X can be any amino acid except proline (Pro, P).

N-glycan Common name of an N-linked glycan.

Introduction

The first structures of N-glycans were determined in the 1970s using a combination of biochemical strategies to identify the sugars attached to Asn in certain glycoproteins, and their linkage arrangements. The glycans released from glycoproteins contained several monosaccharides, including N-acetylglucosamine (GlcNAc), mannose (Man), galactose (Gal), fucose (Fuc), and sialic acid (NeuAc). However, the composition gave only the slightest clue as to the origins of these complex structures. The N-glycans could be divided into three types – complex, hybrid and high mannose N-glycans (Figure 1). The clue to their origin was that each N-glycan type contains the same core region consisting of two GlcNAc and three Man residues. Determining how the common core of N-glycans is synthesized required much careful work because it was quickly revealed that precursors contain glucose (Glc), a

sugar almost never found in mature N-glycans of glycoproteins from a healthy cell. This article describes each stage of N-glycan synthesis from initiation on dolichol-phosphate (Dol-P) on the cytosolic face of the endoplasmic reticulum (ER); to the synthesis of a 14-sugar precursor attached to dolichol-pyrophosphate on the luminal face of the ER membrane; the en-bloc transfer of the mature oligosaccharide to Asn in a conserved amino acid sequence; the processing or trimming to remove sugars in an ordered progression that begins in the ER; the continued synthesis and processing in the *cis*- and *medial*-Golgi compartments; and final maturation in the *trans*-Golgi and *trans*-Golgi network (TGN) compartments. It is a complicated pathway involving all the basic building blocks of the cell – lipids, proteins, nucleic acids, and sugars. Therefore, defects in many different aspects of cell metabolism may cause altered synthesis of N-glycans, which may in turn lead to human disease. A large group of diseases included in the

Figure 1 Typical N-glycans. Glycoproteins on the plasma membrane or secreted from the cell may carry high mannose, hybrid, or complex N-glycans. High mannose N-glycans may have fewer than 9 Mans, hybrid N-glycans may also contain only 3 Mans, and complex N-glycans may have varying numbers of branches, lactosamine units, and terminal modifications. Each N-glycan has a common core of Man₃GlcNAc₂. LeX and SLeX determinants are noted. Blue square, GlcNAc; green circle, Man; yellow circle, Gal; purple diamond, sialic acid; red triangle, Fuc. This Figure is modified from Figure 8.1, and reproduced with permission of the Consortium of Glycobiology editors from Chapter 8, Stanley, P., Schachter, H., Taniguchi, N., 2009. N-Glycans. In: Varki, A., Cummings, R.D., Esko, J.D., *et al.* (Eds.), *Essentials of Glycobiology*, second ed. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, pp. 101–114.

Congenital Disorders of Glycosylation (CDG) have been shown to arise from defective N-glycan synthesis.

Initiation of an N-Glycan on Dolichol-Phosphate

Contrary to expectations, the synthesis of an N-glycan begins on the cytosolic face of the ER membrane. Dolichol-phosphate (Dol-P), a polyprenol containing 15–20 unsaturated isoprene units, is located in the ER membrane with the monophosphate unit accessible to the cytosol. The first reaction of N-glycan synthesis is the transfer of phospho-GlcNAc from the nucleotide sugar UDP-GlcNAc to Dol-P, to form Dol-P-P-GlcNAc (Figure 2). All subsequent reactions in N-glycan synthesis involve the sequential addition of monosaccharides to form linear or branched sugar chains. The next sugar added is GlcNAc from UDP-GlcNAc and then three Man residues are added from GDP-Man (Figure 2). Each sugar is added at a precise location and each sugar transfer is catalyzed by a unique glycosyltransferase encoded in a single gene. Many of the enzymes are named ALG for Asparagine-Linked Glycosylation. The Dol-P-oligosaccharide with five sugars is 'flipped' across the ER membrane so that the sugars now face the lumen of the ER (Figure 3).

Maturation of the Dol-P-P-Oligosaccharide

After flipping of the Dol-P-P-oligosaccharide across the ER membrane, four additional Man residues and three Glc residues are added (Figure 3). Importantly, these sugars are all added from Dol-P-Man or Dol-P-Glc, respectively. This form of activated sugar substrate for ER glycosyltransferases is made on the cytosolic face of the ER membrane. Dol-P receives Man or Glc from GDP-Man or UDP-Glc, respectively, and the

Dol-P-sugar is 'flipped' across the ER membrane to become Dol-P-Man or Dol-P-Glc substrate. Each glycosyltransferase that adds the 4 Man and 3 Glc residues is encoded by a different gene. The mannosyltransferases and glucosyltransferases that catalyze these reactions are multi-membrane spanning proteins. The mature Dol-P-P-oligosaccharide contains 7 core sugars added in the cytosol and 7 additional sugars added in the ER to form 14 sugars linked to Dolichol (Dol-P-P-GlcNAc₂Man₉Glc₃) (Figure 3).

En-Bloc Transfer of an N-Glycan to Protein

The mature Glc₃Man₉GlcNAc₂ oligosaccharide is transferred, for the most part co-translationally, to certain Asn residues of a protein during its synthesis and after passage into the ER lumen via a translocon. The translocon is a large complex of proteins that includes the subunits of oligosaccharyltransferase (OST), the activity that recognizes Asn residues to receive an N-glycan. The minimal consensus sequence for the receipt of the Glc₃Man₉GlcNAc₂ oligosaccharide is Asn-X(not Pro)-Ser/Thr. Glycoproteomics studies have revealed Asn-X-Cys as a rare site of N-glycosylation and some non-consensus sites (Zielinska *et al.*, 2010). Asn residues in these sequons are termed putative N-glycan sites. This is because not all such sites are accessible to OST and thus not all putative sites receive an N-glycan. This may be due to conformational restrictions, or to the speed of passage past OST, or to blockage of access by other proteins. Attempts to broaden the consensus sequence in order to add N-glycosylation sites to proteins to aid in their folding and stability have identified enhanced aromatic sequons that may be efficiently N-glycosylated (Price *et al.*, 2012). Dol-P-P-oligosaccharides that contain fewer than 14 sugars may arise if glucose is limiting, due to altered expression of biosynthetic enzymes or due to ER stress. Such

Figure 2 N-glycan synthesis begins on the cytosolic face of the ER. Dol-P is the substrate for DPAGT1 that initiates N-glycan synthesis by transferring P-GlcNAc from UDP-GlcNAc to generate Dol-P-P-GlcNAc. The subsequent addition of each sugar is catalyzed by the enzymes shown. Dol-P-P-GlcNAc₂Man₅ is flipped across the ER membrane and subsequent reactions occur on the lumenal face of the ER membrane. Blue square, GlcNAc; green circle, Man. Enzymes in red are named according to the recommendation of the Human Genome Nomenclature Committee. This Figure is modified from Figure 8.3, and reproduced with permission of the Consortium of Glycobiology editors from Chapter 8, Stanley, P., Schachter, H., Taniguchi, N., 2009. N-Glycans. In: Varki, A., Cummings, R.D., Esko, J.D., *et al.* (Eds.), *Essentials of Glycobiology*, second ed. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, pp. 101–114.

Figure 3 N-glycan transfer to protein. The Dol-P-P-GlcNAc₂Man₅ that is flipped across the ER membrane is the substrate of a mannosyltransferase that transfers Man from Dol-P-Man, which is also flipped across the ER membrane. Three more Mans are added before the addition of Glc from Dol-P-Glc by glucosyltransferases. This 14-sugar N-glycan Dol-P-P-GlcNAc₂Man₉Glc₃ is transferred 'en bloc' to accessible Asn residues in the sequon Asn-X(not Pro)-Ser/Thr during translocation of nascent protein into the ER. The oligosaccharyltransferase (OST) that catalyzes N-glycan transfer is a complex of many subunits. Blue square, GlcNAc; blue circle, Glc; green circle, Man. Enzymes in red are named according to the recommendation of the Human Genome Nomenclature Committee. This Figure is modified from Figure 8.3, and reproduced with permission of the Consortium of Glycobiology editors from Chapter 8, Stanley, P., Schachter, H., Taniguchi, N., 2009. N-Glycans. In: Varki, A., Cummings, R.D., Esko, J.D., *et al.* (Eds.), *Essentials of Glycobiology*, second ed. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, pp. 101–114.

truncated Dol-P-P-oligosaccharides may be transferred to Asn, but with reduced efficiency. Many empty N-glycan sites will arise if little or no extension of the core Dol-P-P-oligosaccharide occurs. In this case, proteins will be poorly folded and subject to ER degradation.

Processing and Folding of Glycoproteins in the ER

During folding of a nascent glycoprotein, the N-glycans and glycan binding chaperones that recognize N-glycans, play an important role in quality control. The first step in N-glycan processing is removal of the terminal Glc residue by a membrane-bound α -glucosidase, MOGS (Figure 4). The next Glc is removed by a soluble α -glucosidase (GANAB) that generates Glc₁Man₉GlcNAc₂ recognized by the membrane-bound chaperone calnexin or the soluble chaperone calreticulin (Figure 4). Protein disulfide isomerase (PDI) ERp57 is also in this complex. As folding continues, the last Glc residue is removed by GANAB. If folding is still incomplete following Glc removal, a glucosyltransferase (UGGT) binds to exposed hydrophobic patches on glycoproteins and reglucosylates Man₉GlcNAc₂ N-glycans to restore Glc₁Man₉GlcNAc₂ that may be chaperoned again by calnexin/ERp57 or calreticulin. This cycle of removal and re-addition of a Glc residue continues until folding is optimal. The Man₉GlcNAc₂ N-glycan on correctly folded glycoproteins is recognized by XTP3-B, a protective chaperone that may stabilize glycoproteins. Once folding is of high quality, an ER mannosidase (ERMAN1) removes the central, terminal Man residue to generate Man₈GlcNAc₂ that is recognized by ERGIC-53 in the complex LMAN1/MCFD2 and escorted from the ER to the ER-Golgi intermediate compartment (ERGIC). This occurs for both soluble and membrane-bound glycoproteins.

If appropriate folding fails to occur, several chaperones assist in the removal of misfolded glycoproteins from the ER.

For glycoproteins that are misfolded early after synthesis, removal of the first Glc generates a recognition determinant for a complex between membrane-bound malectin (MLEC) that recognizes Glc₂Man₉GlcNAc₂ and ribophorin 1 (RPN1), a subunit of OST that recognizes misfolded protein. The misfolded glycoprotein is translocated to the cytoplasm for degradation by the proteasome. If appropriate folding has not been achieved after the last Glc residue has been removed, the glycoprotein is subjected to ER-associated degradation (ERAD). Removal of two Man residues from Man₉GlcNAc₂ by ER degradation enhancing mannosidase-like protein 3 (EDEM3), results in binding of OS-9 to Man₇GlcNAc₂ N-glycans. OS-9 is in a complex with an ER ubiquitin ligase, and assists in escorting the unfolded glycoprotein from the ER for degradation by the proteasome. EDEM1 and EDEM2 also bind to N-glycans and assist in ERAD. NGLY1 is a cytosolic N-glycanase that removes N-glycans prior to degradation by the proteasome. All N-glycans in the ER are sensitive to bacterial endoglycosidase H (Endo H), which cleaves between the two core GlcNAc residues leaving a single GlcNAc attached to Asn. To date no mammalian gene encoding an Endo H activity has been reported.

Unique Modification of Lysosomal Hydrolases

Lysosomal hydrolases that will become residents of lysosomes are recognized in the *cis*-Golgi by a complex enzyme with phospho-GlcNAc-transferase activity. The enzyme is composed of two alpha and beta subunits (GNPTAB) and two gamma subunits (GNPTG), and transfers phospho-GlcNAc from UDP-GlcNAc to the high mannose N-glycans of lysosomal hydrolases (Figure 5). Following passage to the *trans*-Golgi, the terminal GlcNAc is removed by an N-acetylglucosaminidase (NAGPA) and the exposed Man-P is recognized by a Man-6-P

Figure 4 N-glycan processing and glycoprotein folding in the ER. Following transfer by OST to protein, the α -glucosidase MOGS binds to the N-glycan. Processing of the N-glycan begins when the terminal Glc is removed by MOGS, generating an N-glycan recognized by the chaperone complex RPN1/MLEC. Removal of the next Glc generates a recognition determinant for calnexin/calreticulin/ERp57 which assist in glycoprotein folding. When all 3 Glc residues have been removed, the partially folded glycoprotein is usually recognized by the unfolded glycoprotein glucosyltransferase UGGT, re-glucosylated and chaperoned by calnexin in a cycle until appropriate folding has been achieved. If that is never achieved, the glycoprotein is either degraded in the ER by ERAD, or in the cytoplasm by the proteasome. Properly folded glycoproteins have one Man removed and are escorted to the *cis*-Golgi network (CGN) by LMAN1/MCFD2. Blue square, GlcNAc; blue circle, Glc; green circle, Man. Enzymes in red and lectin chaperones in black are named according to the recommendation of the Human Genome Nomenclature Committee. This Figure is modified from Figure 8.4, and reproduced with permission of the Consortium of Glycobiology editors from chapter 8, Stanley, P., Schachter, H., Taniguchi, N., 2009. N-Glycans. In: Varki, A., Cummings, R.D., Esko, J.D., *et al.* (Eds.), *Essentials of Glycobiology*, second ed. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, pp. 101–114.

receptor (MPR) which escorts the lysosomal hydrolase to the lysosome (Figure 5). The Man-6-P receptor is released in the acidic environment of the endosome and cycles between the Golgi, endosomes and the plasma membrane. Mutations in enzymes that generate the Man-6-P recognition determinant lead to lysosomal storage diseases including I-cell disease (MPSII and MPSIIIA).

Maturation of N-Glycans During Transit Through Golgi Compartments

Processing of the N-glycans on glycoproteins continues in the *cis*-Golgi compartment (Figure 5). If high mannose N-glycans on a glycoprotein still carry one or more Glc residues that were not removed in the ER, a Golgi endo-mannosidase will cleave between Man residues to release Glc₁₋₃Man. Terminal Man residues are removed by class I Golgi mannosidase MAN1A2 to generate the Man₅GlcNAc₂ substrate for MGAT1 which transfers GlcNAc from UDP-GlcNAc, to generate a hybrid N-glycan in the *medial*-Golgi compartment. If not further processed, the hybrid N-glycan can be extended by the addition of Gal to GlcNAc and of sialic acid to Gal (Figure 1). More typically, the N-glycan product of MGAT1 is trimmed by removal of two Man residues by a class II mannosidase MAN2A1 which generates the substrate for MGAT2. In the

absence of MGAT2, the GlcNAc on the Man₃ hybrid N-glycan can be extended with Gal and sialic acid. Transfer of GlcNAc from UDP-GlcNAc by MGAT2 generates a biantennary, complex N-glycan that is a substrate for many glycosyltransferases. In the *medial*-Golgi, additional GlcNAc residues may be added via MGAT3 to generate a bisected N-glycan, or MGAT4, MGAT5, MGAT6 to generate branched, complex N-glycans (Figure 1). In the *trans*-Golgi, the GlcNAc linked to Asn may receive a Fuc transferred from GDP-Fuc by FUT8 (Figure 5). Terminal GlcNAc residues on complex N-glycans are the substrate for galactosyltransferases including B4GALT1. Gal is usually added to all terminal GlcNAcs of complex or hybrid N-glycans in the *trans*-Golgi. Gal residues on complex or hybrid N-glycans in the *trans*-Golgi or the TGN are substrates for sialyltransferases such as ST3GAL1, that transfer sialic acid from CMP-sialic acid. There are at least 5 sialyltransferases that act on Gal residues of complex N-glycans. Finally, there are fucosyltransferases in the *trans*-Golgi and TGN that transfer Fuc from GDP-Fuc to the GlcNAc in Gal β 1,4GlcNAc (lactosamine) units. The trisaccharide Gal β 1,4GlcNAc(α 1,3Fuc) is the Lewis X (LeX) oncofetal antigen, whereas Neu α 2,3Gal β 1,4GlcNAc(α 1,3Fuc) is the sialyl-Lewis X (SLeX) antigen (Figure 1). SLeX is a key recognition determinant for selectins that allow endothelial cells to recruit lymphocytes to roll on the endothelium prior to extravasation into tissues. In certain cell types, Gal and GlcNAc residues can be modified by sulfotransferases.

Figure 5 N-glycan maturation in the Golgi. For most glycoproteins, processing of the high mannose N-glycan continues in the *cis*-Golgi. However, for lysosomal hydrolases destined for the lysosome, the high mannose N-glycan is a substrate for a phospho-GlcNAc-transferase which transfers P-GlcNAc, precluding further processing on that branch. For most glycoproteins, 3 MANS are removed to form Man₅GlcNAc₂, and then complex and hybrid N-glycan synthesis is initiated by MGAT1. Subsequent removal of 2 MANS and elongation by the addition of GlcNAc, Gal and sialic acid (NeuAc) leads to the generation of complex N-glycans. Blue square, GlcNAc; blue circle, Glc; green circle, Man; yellow circle, Gal; purple diamond, sialic acid; red triangle, Fuc. Enzymes in red are named according to the recommendation of the Human Genome Nomenclature Committee. This Figure is modified from Figure 8.4, and reproduced with permission of the Consortium of Glycobiology editors from Chapter 8, Stanley, P., Schachter, H., Taniguchi, N., 2009. N-Glycans. In: Varki, A., Cummings, R.D., Esko, J.D., *et al.* (Eds.), *Essentials of Glycobiology*, second ed. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, pp. 101–114.

Functions of N-Glycans

Chaperones Recognize High Mannose N-Glycans on Unfolded Glycoproteins

In addition to contributing to the physical properties of a glycoprotein in terms of its solubility, resistance to proteases and half-life, particular N-glycan residues, or groups interactions with glycan-binding proteins (GBPs) that regulate the expression, activity and function of a glycoprotein. In the ER, chaperones and enzymes that bind to specific regions of high mannose N-glycans lead to optimal glycoprotein folding, or degradation by ERAD, or ubiquitination and translocation to the cytosol and degradation by the proteasome (Figure 4). Transit from the ER to ERGIC is facilitated by LMAN1/MCFD2 binding to a particular high mannose N-glycan (Figure 5). If a glycoprotein makes it to the *trans*-Golgi with high mannose

N-glycans and in an unfolded state, the mannose-binding lectin VIP36 will deliver it to the chaperone BiP in the ER.

Man-6-P Receptors

Lysosomal hydrolases destined to reside in lysosomes where they degrade proteins, lipids and carbohydrates are escorted through the Golgi compartments and into endosomes by Man-6-P receptors (MPRs) which recognize Man-6-P exposed following removal of the GlcNAc transferred by phospho-GlcNAc-transferase (Figure 5). There are two types of receptor that differ in their dependence on calcium for binding Man-6-P. The cation-independent receptor, CI-MPR, contains 15 Man-6-P receptor homology domains (MRH), each of 150 amino acids, and is a transmembrane glycoprotein that cycles to the cell surface where it binds Insulin-like growth factor II

and retinoic acid in addition to Man-6-P. The cation-dependent MPR (CD-MPR) is much smaller with one MRH domain, a transmembrane and a cytosolic domain. Both MPRs transport lysosomal hydrolases from the *trans*-Golgi to endosomes where the acidic pH causes release of MPRs which recycle to the *cis*-Golgi or go to the plasma membrane.

Functions of Complex N-Glycans at the Cell Surface

The functions of complex N-glycans were discovered using genetic and biochemical strategies. N-glycans are the primary ligands for mammalian lectins such as the galectins that recognize Gal residues. Siglecs bind to sialic acid residues and selectins bind to SLeX (Figure 1). Pathogens such as influenza virus bind to sialic acid, and cell-cell interactions in the nervous system are mediated by polysialic acid on N-CAM. Mutant Chinese hamster ovary (CHO) cells have been useful in determining functions for N-glycans (Table 1). Interestingly, deletion of the *Mgat1* gene in the mouse causes embryonic lethality, whereas cells lacking this enzyme grow well in culture. The severe effects of removing MGAT1 during development may be due to several factors, including the roles complex N-glycans play in regulating growth factor and cytokine signaling via their interactions with galectins. Thus, the branching of complex N-glycans and the length of lactosamine repeats (polylactosamine) on each branch dictates the nature and strength of galectin interactions with N-glycans attached to signaling receptors. Now that new gene targeting technology can readily be applied to mammalian cells, the generation of precise somatic cell mutants to determine sites of N-glycan modification, N-glycan functions and for use in glycosylation engineering can proceed at an enhanced pace. Similarly, the generation of mouse mutants defective in N-glycan synthesis continues to open many avenues for functional studies.

Functions of Complex N-Glycans on Secreted Glycoproteins

Complex N-glycans on secreted glycoproteins affect their overall properties, solubility, stability, half-life and cell-specific targeting.

Complex N-glycans may be used to target therapeutic glycoproteins to cells with specific glycan binding receptors. Thus, removal of sialic acid to expose terminal Gal residues causes glycoproteins to be rapidly cleared from the circulation by the Ashwell-Morrell receptor (ASGR) in the liver. This may be used as a strategy for targeting therapeutics to liver. Glycoprotein hormones are also targeted to liver for removal from the circulation by recognition of terminal sulfated GalNAc on their complex N-glycans by the mannose/GalNAc-4-SO(4) receptor (MANR) of hepatic endothelial cells. Targeting of lysosomal hydrolases to mannose receptors of reticuloendothelial cells for enzyme replacement therapy in patients with lysosomal storage diseases is enhanced by preparing enzymes that carry only high mannose N-glycans. Cytotoxic IgG antibodies are made ~1000 times more cytotoxic if the core Fuc residue of the complex N-glycan in the hinge region is not added. Immune IgG serum used in passive immunization of patients with auto-immune disease is more active as an anti-inflammatory treatment than if it is fully sialylated.

Summary

Since the discovery of dolichol-linked sugars in the late 1970s, the complexity of N-glycan synthesis has continued to be revealed. Activities still remain to be discovered, such as one or more flippases responsible for translocating Dol-P-sugars to face the lumen of the ER (Figures 2 and 3). Nevertheless, the last 35 years has led to enormous progress in the identification of a large number of genes that code for activities required for N-glycan synthesis. The enzymes and transporters noted in the figures represent the major activity known to catalyze each reaction. However, for some enzymes such as the mannosidases, more than one isozyme exists. N-glycan synthesis begins on the cytosolic face of the ER membrane (Figure 2), continues in the lumen of the ER (Figure 3), then moves to the *cis*-Golgi network (CGN) and processing and maturation proceeds during transit through the Golgi compartments.

Abbreviation: GC, glycoconjugate.

Glycan binding chaperones with lectin domains assist folding, removal of unfolded proteins in the ER, and transport to the CGN. In the Golgi, lysosomal hydrolases are escorted by MPRs through the Golgi to endosomes and VIP36 recognizes unfolded glycoproteins with high mannose N-glycans and returns them to the ER. It seems likely that additional glycan binding chaperones will be found in the Golgi. The N-glycans that end up on a mature glycoprotein may be very heterogeneous. They may comprise all three classes of N-glycan and many variants of each. This complexity is being revealed by glycomics and glycoproteomics mass spectrometry. However, it is clear that specific functions of individual sugars or groups of sugars on N-glycans operate in a sea of background heterogeneity. An excellent example is the recognition of SLeX on P-selectin glycoprotein ligand 1 (PSGL-1) which requires SLeX to be present on an O-glycan attached to a specific Thr near the N-terminus of PSGL-1, and which also requires sulfated tyrosine residues nearby. The fact that many other N- and O-glycans on PSGL-1 may carry SLeX is of little or no benefit if the N-terminal recognition determinant is absent. For this reason, finding the functional glycan unit using a biochemical strategy alone is very difficult. Genetic strategies in combination with biochemistry are much more efficient.

Glossary

Delta Cell surface-anchored ligand that binds to the Notch receptor, thereby initiating conserved signaling cascades.

Glycosylation The act of modifying proteins or other macromolecules through the covalent attachment of carbohydrates.

Hyperphosphatemia Abnormally high levels of phosphate in the blood.

Integrins Transmembrane proteins that mediate cell attachment and conserved signaling events that regulate cell shape, adhesion, and migration.

Notch Transmembrane receptor protein that initiates a conserved signaling cascade upon binding to the ligands Serrate or Delta.

Osteochondroma A benign tumor consisting of bone and cartilage.

Proteoglycans Proteins with glycosaminoglycan chains attached.

Serrate Cell surface-anchored ligand that binds to the Notch receptor, thereby initiating conserved signaling cascades.

Spondyloepiphyseal dysplasia Inherited disease characterized by short stature and skeletal abnormalities.

Temtamy preaxial brachydactyly syndrome Autosomal recessive disorder characterized by shortened digits, growth retardation, facial dysmorphism, delayed motor, and mental development.

Introduction

The addition of sugars to the hydroxyl groups of proteins (O-glycosylation) as they transit the secretory apparatus affects the function of diverse membrane-bound and secreted proteins. O-linked glycosylation can occur in many forms and is characterized by the first sugar attached to the protein backbone (Figure 1 and Table 1). The following is a description of the major types of extracellular O-linked glycans, the enzymes responsible for their synthesis, and the known biological functions of these diverse sugar chains.

Mucin-Type O-Glycans/O-GalNAc Glycans

Mucin-type O-glycosylation is characterized by the initial addition of an *N*-acetylgalactosamine (GalNAc) sugar onto the hydroxyl group of either serine or threonine in protein substrates (Figure 2). This type of glycosylation received its name because of its abundance on mucins, proteins that contain repeating domains rich in serine, threonine, and proline. The initial addition of GalNAc is catalyzed by an evolutionarily conserved family of enzymes, known as the UDP-GalNAc: polypeptide *N*-acetylgalactosaminyltransferases (ppGalNAc-Ts in mammals, PGANTs in *Drosophila*) (Bennett *et al.*, 2012; Tran and Ten Hagen, 2013). These enzymes are type II transmembrane proteins present in the Golgi apparatus. There are as many as 20 family members in humans, 19 in mice, and 12 in *Drosophila*. While each family member is capable of transferring GalNAc to protein/peptide substrates, *in vitro* studies have revealed that certain family members have preferences for particular substrates, suggesting that each enzyme may be responsible for modifying specific proteins *in vivo*. Additionally, gene expression studies have revealed that certain family members are expressed in specific temporal and spatial

patterns, suggesting that they may have unique roles in certain tissues during eukaryotic development (Kingsley *et al.*, 2000; Tian and Ten Hagen, 2006).

The further addition of other sugars, such as galactose (Gal), *N*-acetylglucosamine (GlcNAc), or GalNAc, forms extended core structures, some of which are shown in Figure 2. Core 1 or T antigen is the most common O-GalNAc glycan in mammals and is formed by the Core 1 β 1,3-galactosyltransferase (C1GalT1 or T-synthase). The core structures can be further extended and modified by the addition of GlcNAc, Gal, and fucose (Fuc). Finally, the addition of charged sugars (sialic acid in mammals and glucuronic acid (GlcA) in *Drosophila*) at the end of each chain can confer properties to the glycans and their associated proteins reflective of an increased negative charge.

Mucin-type O-glycans have been found to have diverse biological roles. Early *in vitro* and cell culture work demonstrated that O-GalNAc glycans play important roles in maintaining the physical and chemical properties of proteins (Tabak, 1995). O-GalNAc glycans serve as important ligands

Figure 1 Extracellular O-Glycans. The major types of O-linked glycosylation initiated in the Golgi apparatus or endoplasmic reticulum (ER) are shown. S, serine; T, threonine; Hyl, hydroxylysine.

Table 1 Different types of extracellular O-glycans

Type of O-glycan	Core structure and linkage	Enzyme responsible
O-GalNAc	GalNAc α 1-Ser/Thr	ppGalNAcTs
O-Mannose	Man α 1-Ser/Thr	POMT1/2
O-Fucose	Fuc α 1-Ser/Thr	POFUT1/2
O-Glucose	Glc β 1-Ser	POGLUT
O-GlcNAc	GlcNAc β 1-Ser/Thr	EOGT
O-Galactose	Gal β 1-Hyl	GLT25D1/2
O-Xylose	Xyl β 1-Ser	XYLT1/2

Abbreviations: GalNAc, *N*-acetylgalactosamine; Man, mannose; Fuc, fucose; Glc, glucose; Gal, galactose; Xyl, xylose; ppGalNAcTs, UDP-GalNAc:polypeptide *N*-acetylgalactosaminyltransferases; POMT1/2, protein O-mannosyltransferase 1 and 2; POFUT1/2, protein O-fucosyltransferase 1 and 2; POGLUT, protein O-glucosyltransferase; EOGT, EGF repeat-specific O-GlcNAc transferase; GLT25D1/2, glycosyltransferase 25 family member 1/2; XYLT1/2, xylosyltransferase 1 and 2; Ser, serine; Thr, threonine; Hyl, hydroxylysine.

**Figure 2** Mucin-Type O-Glycans/O-GalNAc Glycans. The enzymes responsible for the synthesis of mucin-type O-glycans and the common core structures are shown.

for molecular recognition involved in lymphocyte homing (Yago *et al.*, 2010; Tenno *et al.*, 2007; Block *et al.*, 2012). Many studies in model organisms have identified crucial roles for O-glycans during development as well. Studies from *Drosophila* demonstrated that O-glycans are essential for development (Tran *et al.*, 2012; Bennett *et al.*, 2012; Tran and Ten Hagen, 2013). Further, O-glycans are essential for epithelial tube formation in the respiratory tract (Tian and Ten Hagen, 2007), nervous system development (Lin *et al.*, 2008), and integrin-mediated cell adhesion (Zhang *et al.*, 2008). It was further determined that the loss of mucin-type O-glycosylation affected the secretion of extracellular matrix (ECM) proteins during *Drosophila* development, leading to a disruption in integrin-mediated cell adhesion (Zhang *et al.*, 2010). The effects of O-GalNAc glycans on secretion of ECM proteins during development was also verified in mice, where loss of

ppGalNAcT-1 resulted in a disruption of basement membrane secretion, resulting in reduced integrin and FGF signaling, induction of ER stress, and reduced organ growth (Tian *et al.*, 2012). Most recently, studies in *Drosophila* demonstrated that O-glycosylation influences secretion by protecting an essential component of the secretory apparatus (Tango1) from proteolysis (Zhang *et al.*, 2014). Other studies suggest that O-GalNAc glycans may influence TGF β signaling (Herr *et al.*, 2008) and also Notch signaling, where they influence left-right patterning during development (Boskovski *et al.*, 2013).

Core 1-derived O-glycans are involved in angiogenesis (Xia *et al.*, 2004), separation of blood and lymphatic vessels during embryonic and postnatal development (Fu *et al.*, 2008), and proper platelet biogenesis and function (Alexander *et al.*, 2006; Wang *et al.*, 2012). Loss of core 3 O-glycans resulted in increased susceptibility to colitis and colon cancer (An *et al.*, 2007). Loss of core 1-derived O-glycans lead to spontaneous colitis in mice, supporting a protective function for O-glycans for intestinal health (Fu *et al.*, 2011; Bergstrom and Xia, 2013).

Recent genetic linkage and genome wide association studies have found associations between the enzymes involved in the synthesis of mucin-type O-glycans and various human diseases and predispositions to disease. Diseases resulting from mutations in genes involved in glycan biosynthesis are collectively known as congenital disorders of glycosylation (CDGs). For example, mutations in GALNT3 in humans are responsible for the CDG known as familial tumoral calcinosis, characterized by hyperphosphatemia, bone density changes, and subdermal calcified tumors (Topaz *et al.*, 2004). It is hypothesized that GALNT3 normally glycosylates the phosphate-regulating hormone fibroblast growth factor 23 (FGF23) to protect it from proteolysis. Other studies have suggested links between the genes initiating mucin-type O-glycosylation and other human conditions, including blood cholesterol levels (GALNT2); acute coronary syndrome (GALNT4); heterotaxy (GALNT11); breast and colorectal cancers (GALNT5 and GALNT12), suggesting crucial roles for these glycans in many aspects of human health and disease (Bennett *et al.*, 2012; Tran and Ten Hagen, 2013). Future studies will focus on identifying the molecular mechanism by which these glycans function in both developing systems as well as in adult tissues.

O-Mannose Glycans

O-linked mannose (O-Man) glycans are found on a limited number of proteins, but have been extensively studied on the extracellular protein α -dystroglycan. α -Dystroglycan comprises the extracellular portion of the dystrophin-glycoprotein complex, which is responsible for linking the extracellular matrix to the cytoskeleton and thus maintaining the integrity of muscle cells. O-linked mannose glycans present on α -dystroglycan are required for binding ECM proteins, such as laminin, agrin, and perlecan. Loss or disruption of α -dystroglycan glycosylation results in various CDGs known as congenital muscular dystrophies (CMDs) (also known as dystroglycanopathies), highlighting the importance of these glycans in human biology (Wells, 2013). Human diseases such as Walker-Warburg syndrome (WWS), muscle-eye-brain disease (MEB), and Fukuyama congenital muscular dystrophy

(FCMD), which present with varying degrees of neurological defects and muscle degeneration, are associated with mutations in the enzymes responsible for forming O-linked mannose chains on α -dystroglycan (Wells, 2013; Nakamura *et al.*, 2010; Hennet, 2012).

The initial addition of mannose to the hydroxyl groups of either serine or threonine residues occurs through the action of protein O-mannosyltransferase 1 (POMT1) and 2 (POMT2). POMT1 and POMT2 are integral membrane proteins that are localized to the ER, where mannose addition takes place. Both enzymes are required for the initial addition of mannose, suggesting that they function as a heterocomplex. Mutations in these genes cause CMDs, including WWS, one of the most severe forms of muscular dystrophy. The *Drosophila* orthologues of POMT1 and POMT2 similarly add mannose to *Drosophila* dystroglycan and result in muscle abnormalities when mutated (Nakamura *et al.*, 2010).

Diverse chain extensions can occur from the initial mannose sugar and are produced by the action of a number of different enzymes that add sugars in a step-wise fashion. Chain extension is carried out by POMGnT1, a β 1,2-N-acetylglucosaminyltransferase. POMGnT1 is a Golgi-resident type II transmembrane protein that adds GlcNAc to the extant mannose in a β 1,2 linkage. Mutations in this enzyme are also responsible for various forms of congenital muscular dystrophies (CMD) in humans (Wells, 2013). Formation of branched O-mannose glycans occurs through the activity of another Golgi-resident enzyme GlcNAcT-Vb, which adds GlcNAc in a β 1,6 linkage to mannose. Branched mannose

chains (and GlcNAcT-Vb activity) are primarily confined to the brain. Recent studies have identified another N-acetylglucosaminyltransferase (POMGnT2) that forms a β 1,4 linked GlcNAc to the extant mannose (Yoshida-Moriguchi *et al.*, 2013). This disaccharide can then be extended by the β 1,3-N-acetylgalactosaminyltransferase2 (B3GALNT2) to form a linear trisaccharide (Yoshida-Moriguchi *et al.*, 2013). It is believed that this trisaccharide serves as the substrate for phosphorylation by the atypical kinase, SGK196 or POMK, to form a phosphorylated O-mannose-based glycan. Subsequent extension of some form of this phosphorylated glycan by the enzyme LARGE further elaborates O-mannose chains (Inamori *et al.*, 2013). LARGE is unique in that it is a bi-functional enzyme with 2 independent glycosyltransferase domains. One domain is responsible for the addition of xylose to GlcA and the other is responsible for the addition of GlcA to xylose, thus making LARGE capable of adding repeating disaccharides to the phosphorylated O-mannose chains (Figure 3). Studies suggest that these repeating disaccharides are responsible for mediating binding to ECM proteins. Mutations in LARGE result in CMDs. Finally, mutations in two additional proteins responsible for the formation of O-mannose glycans, Fukutin and FKRP, also result in CMDs. While they likely contribute to the elaboration of the O-mannose chains, their biochemical activities and specific functions are currently unknown (Wells, 2013).

In addition to α -dystroglycan, recent studies have identified O-mannose glycans on additional proteins, including the cell adhesion proteins, cadherin, and plexin (Vester-Christensen

Figure 3 O-Mannose glycans. The enzymes involved in the synthesis of O-linked mannose structures are shown.

et al., 2013). It has further been found that the O-mannose glycans present on cadherin are essential for cadherin-mediated cell adhesion during early mouse embryogenesis (Lommel *et al.*, 2013).

O-Fuc Glycans

There are two distinct enzymes responsible for the addition of O-linked fucose to proteins: O-fucosyltransferase 1 (Pofut1 in mammals or Ofut1 in *Drosophila*) and O-fucosyltransferase 2 (Pofut2 in mammals or Ofut2 in *Drosophila*) (Luo *et al.*, 2006). Ofut1 is a soluble ER-localized enzyme that transfers O-linked fucose to the EGF repeats of Notch and its ligands, Delta and Serrate, recognizing the consensus motif, $C_2X_{4-5}(S/T)C_3$ (Rana and Haltiwanger, 2011). After the addition of O-fucose, the Golgi-localized $\beta 1,3$ -N-acetylglucosaminyltransferase Fringe (Fng in *Drosophila*) adds GlcNAc to the O-fucose (Stanley and Okajima, 2010). Further elongation of the GlcNAc $\beta 1$ -3Fuc can occur in mammals through the addition of galactose and sialic acid (Figure 4). Genetic studies in both the *Drosophila* and mammals have revealed the biological importance of the O-fucose glycans in conserved aspects of Notch signaling and function. Mutations in POFUT1 have been found in patients with Dowling–Degos disease, a pigmentation disorder thought to be due to defects in Notch function (Li *et al.*, 2013). Loss of O-Fuc glycans on mouse Notch1 leads to defects in T cell development and embryogenesis (Ge and Stanley, 2008). Likewise, loss of O-fucose in the fly affects Notch signaling during development. Interestingly, Ofut1 in the fly may also serve in a chaperone capacity for Notch folding or cell-surface expression, independent of its ability to transfer O-linked fucose to Notch (Rana and Haltiwanger, 2011). Studies in both mammals and *Drosophila* identified Fng as a regulator of Notch signaling. Fng expression enhances activation of Notch by the ligand Delta while inhibiting activation mediated by the ligand Serrate (Stanley and Okajima, 2010; Rana and Haltiwanger, 2011). These effects are thought to occur by Fng altering the binding between Notch and its ligands. Additionally, it was found that O-Fuc glycans, especially the structure elongated by Fringe, can affect the structure of Notch (Rana and Haltiwanger, 2011).

Pofut2 adds O-fucose to the consensus motif, $CX_2-3(S/T)CX_2G$ in the thrombospondin type 1 repeats (TSRs), which are

found in many extracellular matrix proteins, such as thrombospondin 1, properdin, f-spondin, ADAMTS-like 1, and ADAMTS-13 (Luo *et al.*, 2006; Heinonen and Maki, 2009). The O-Fuc modification catalyzed by Pofut2 can then be extended by a $\beta 1,3$ -glucosyltransferase that adds glucose to form the disaccharide structure, Glc $\beta 1$ -3Fuc. These glycans are involved in protein interactions and are required for the proper protein folding (Luo *et al.*, 2006). Mutations in this glucosyltransferase result in abnormal O-Fuc glycans on TSRs and lead to Peters Plus syndrome (Hess *et al.*, 2008), a human CDG characterized by short stature, irregular facial features, and mental retardation. Defects in O-fucosylation lead to impaired secretion of the proteases ADAMTS-like 1/punctin 1 (Wang *et al.*, 2007) and ADAMTS-13 (Ricketts *et al.*, 2007). Another recent study found that mutations in Pofut2 caused impaired epithelial to mesenchymal transition, cell movement, and signaling during mouse gastrulation, suggesting the O-Fuc glycans are essential for the formation of a proper extracellular environment (Du *et al.*, 2010).

O-Glc Glycans

O-glucose glycans were recently identified on the EGF repeats of Notch. Protein O-glucosyltransferase 1 (Poglut1 in mammals or Rumi in *Drosophila*) (Acar *et al.*, 2008), a soluble ER-localized enzyme, catalyzes the transfer of glucose to serine (Ser) in the conserved sequence $C_1XSX(P/A)C_2$ (Rana and Haltiwanger, 2011). The O-Glc can be elongated by the addition of a xylose sugar, through the activity of the Golgi-resident type II transmembrane glucoside $\alpha 1$ -3xylosyltransferases, GXYLT1, and GXYLT2 (Sethi *et al.*, 2010). The Xyl $\alpha 1$ -3Glc disaccharide can then be further elongated by the addition of another xylose by the xylosyltransferase 1, XXYL1 (Sethi *et al.*, 2012).

The *rumi* gene was originally identified in a screen for genes that affect Notch signaling (Acar *et al.*, 2008). Mutations in *rumi* resulted in developmental defects related to disruption of Notch signaling (Acar *et al.*, 2008). Similar to what was seen for POFUT1 in humans, mutations in POGLUT1 were also found in patients suffering from Dowling–Degos disease, suggesting a role in Notch function. In mice, loss of Poglut1 resulted in early embryonic lethality and severe growth retardation along with defects in cardiovascular and neural development (Fernandez-Valdivia *et al.*, 2011). Recent studies have shown that mouse Notch1 activity is greatly affected by loss of the O-Glc modification at specific positions. Interestingly, loss of O-Glc does not appear to affect Notch cell-surface expression or ligand binding. Rather, O-Glc affected Notch proteolysis that is required for proper signaling. These studies suggest that O-Glc on the extracellular domain of Notch influences conformational changes that are required within that domain to mediate efficient proteolysis (Acar *et al.*, 2008; Fernandez-Valdivia *et al.*, 2011). In contrast to the positive effects of O-Glc on Notch function, the addition of xylose appears to inhibit Notch function (Lee *et al.*, 2010).

While Notch is known to contain O-Glc on its EGF repeats, bioinformatic analysis based on the consensus sequences of O-Glc addition suggests there are other proteins that contain this sugar modification. This thought is supported by studies

Figure 4 O-Fucose glycans. O-fucose structures initiated by Pofut1 (EGF repeats) and Pofut2 (TSR repeats) are shown.

showing that loss of Poglut1/Rumi results in phenotypes that are more severe than those seen upon loss of Notch (Fernandez-Valdivia *et al.*, 2011; Rana and Haltiwanger, 2011). Future studies will elucidate additional O-Glc containing proteins and how this sugar modification affects their biological functions.

O-GlcNAc Glycans

The addition of O-linked GlcNAc to cytoplasmic and nuclear proteins has been well documented (Hart *et al.*, 2011). However, recent studies have demonstrated that O-linked GlcNAc is also present on proteins destined for the extracellular environment. This modification is catalyzed by the ER-resident enzyme Eogt (EGF repeat-specific O-GlcNAc transferase), which generates β -linked GlcNAc attached to serine or threonine on substrate proteins (Sakaidani *et al.*, 2012). This modification was originally found on the EGF repeats of the Notch receptor and subsequently, on the ligands, Delta and Serrate in *Drosophila* (Muller *et al.*, 2013). The mouse orthologue of Eogt has a similar enzymatic activity and can glycosylate the mammalian Notch1 EGF domain (Sakaidani *et al.*, 2012).

The functional role of O-GlcNAc addition by Eogt is under investigation. The effects of O-GlcNAc modification of Notch in mammals is still unknown. However, mutations in the human EOGT have been found in patients with Adams–Oliver syndrome, an autosomal recessive disorder characterized by defects in the cranium and limbs (Shaheen *et al.*, 2013). In *Drosophila*, Eogt has also been found to glycosylate a membrane-anchored extracellular protein, Dumpy, and regulate Dumpy-dependent epithelial cell–matrix interaction (Sakaidani *et al.*, 2011), suggesting that extracellular O-GlcNAc glycans may be involved in cell–matrix or cell–cell interactions. However, other studies in *Drosophila* suggest that Eogt activity on Dumpy and Notch may influence their ability to regulate pyrimidine biosynthesis within cells (Muller *et al.*, 2013).

O-Gal Glycans

O-galactose glycans are found predominantly on collagens, one of the major groups of ECM proteins in eukaryotes. These glycans are also found on other proteins, including complement factor C1q, pulmonary surfactant proteins, and mannan binding proteins. What is unique about this type of glycosylation is that it requires hydroxylation of lysine by lysyl hydroxylase (LH1 and LH2) enzymes before galactose addition to this amino acid can occur. After lysine hydroxylation, the β -galactosyltransferases, (GLT25D1 or GLT25D2) add galactose and then the α 1,2-glucosyltransferase (LH3) adds glucose to the galactose, forming the Glc α 1-2Gal disaccharide (Schegg *et al.*, 2009). This modification occurs before collagen is packaged into its triple-helix formation to be secreted.

It is believed that O-Gal glycans are required for many aspects of collagen biosynthesis, secretion, and function (reviewed in Yamauchi and Sricholpech, 2012). Altering collagen O-glycosylation causes developmental defects, including many connective tissue disorders. In *C. elegans*, mutations in the gene

encoding lysyl hydroxylase are embryonic lethal, due to defects in collagen IV secretion. In humans, mutations in the lysyl hydroxylases causes Ehlers–Danlos syndrome type VIa, characterized by defects in the joints and skin; and mutations in LH2 causes Bruck syndrome type 2, characterized by bone fragility and joint contractures. In mice, mutations in LH3 cause embryonic lethality, due to abnormal distribution and aggregation of collagens IV and VI, and impaired basement membrane formation. In humans, the mutations in the ortholog of LH3 (PLOD3) cause congenital connective tissue disorders and epidermolysis bullosa simplex. Altogether, these studies highlight the importance of glycosylation in collagen biosynthesis and function.

Proteoglycans/O-Xyl Glycans

O-xylose addition is the first step in the formation of proteoglycans, proteins to which long linear glycosaminoglycan (GAG) chains are attached. A complete description of their synthesis and biological functions is beyond the scope of this article but is discussed in detail in another article. Additional references are also provided for a comprehensive overview (*Essentials of Glycobiology*, 2nd edition). Briefly, initial xylose addition to the serine residue of substrate proteins is catalyzed by xylosyltransferases (XYLT1 and XYLT2 in mammals and Oxt in *Drosophila*). The xylose is then extended to form the core structure GlcA β 1-3Gal β 1-3Gal β 1-4Xyl. This core structure is extended by the addition of repeating disaccharides, and these chains can then be further modified by the addition of sulfate at specific positions in the constituent sugars to form chondroitin sulfate (CS), dermatan sulfate (DS), heparin sulfate (HS), or heparin.

Proteoglycans are produced by most cells and can exist as either secreted or membrane-bound proteins. Their attached GAGs provide them with unique structural and functional properties, including the ability to bind water and form highly hydrated matrices. Proteoglycan matrices can absorb pressure; serve as scaffolds for ECM and basement membrane organization; regulate permeability of basement membranes; and regulate protease activity. Proteoglycans are also involved in protein–protein and protein–matrix interactions to regulate concentration gradients and endocytosis of bound ligands, thereby affecting cell adhesion, proliferation, differentiation, and motility (*Essentials of Glycobiology*, 2nd edition). Proteoglycans have profound effects on conserved signaling pathways during development. Many studies in model organisms have documented their effects on Hedgehog, Wnt/Wingless, and FGF signaling. There are a number of models that describe the mechanistic role of proteoglycans in signaling events, including: (1) acting as co-receptors to aid in receptor ligand interactions, (2) facilitating dimerization of ligands to aid in receptor binding, and (3) creating developmental gradients of ligands or morphogens by influencing their diffusion, transport, secretion, or stability. Mutations in the genes responsible for proteoglycan biosynthesis are responsible for a number of human diseases and congenital disorders. For example, mutations in β 4GalT-7 causes defective GAG formation of decorin and biglycan, resulting in altered cell migration, adhesion, and wound healing seen in the Ehlers–Danlos

syndrome (Seidler *et al.*, 2006). Additionally, mutations in the enzymes involved in the synthesis of HS, such as EXT1 and EXT2, cause the autosomal dominant disease hereditary multiple exostosis, characterized by bone malformations and osteochondromas (Zak *et al.*, 2002). Alterations in the synthesis of CS cause the CDGs temtamy preaxial brachydactyly syndrome and spondyloepiphyseal dysplasia (Hennet, 2012). Thus, proteoglycans and their associated polysaccharide chains perform crucial roles in diverse cellular and developmental events, and are intimately involved in human health.

Conclusions

O-glycans on extracellular proteins are uniquely positioned to mediate diverse events regulating communication between cells and other cells as well as cells and their surrounding environment. The information described herein highlights the importance of these types of protein modifications in many cellular and developmental processes. Further research in this field will uncover the myriad roles these sugars play in human development, homeostasis, and disease.

Glossary

Anterograde transport The movement of newly synthesized proteins from the site of synthesis to their final destination.

Cisterna Flattened membrane-bound compartment to which a defined set of Golgi resident enzymes localizes and functions.

COPI-coated vesicle 50–70 nm small circular carriers forming at the Golgi that are covered by a complex of COPI subunits forming the COPI coat.

Golgi apparatus One of the key organelle of the secretory pathway made of stacked cisternae (Golgi stack) and two membrane networks on each side of the stack.

Golgi stack A stack of Golgi cisternae.

Secretory pathway The series of membrane-bound compartments allowing the anterograde transport of proteins from the endoplasmic reticulum to the plasma membrane.

Introduction

Cell survival and communication largely depends on the secretion of circulating protein ligands (such as insulin and epithelial growth factor among many others) and plasma membrane receptors that bind these ligands, thus eliciting appropriate signaling pathways triggering growth, differentiation, proliferation, release of biological materials etc. (Farhan and Rabouille, 2011).

Although these ligands and receptors are usually synthesized in different cell types, they have in common to have reached their final destination by trafficking through the secretory pathway. This pathway is made of discrete membrane-bound organelles. The secretory cargo (proteins to be transported through the secretory pathway) are *de novo* synthesized in the endoplasmic reticulum (ER), packaged into COPII-coated carriers at ER exit sites, and transported to the Golgi complex, the central sorting and processing station of secretory cargo proteins of the secretory pathway. The passage through the Golgi ensures that they become biologically active after they are properly glycosylated and processed before being packaged for transport to their final destinations. Note that these destinations are not only the plasma membranes but also the multiple internal membrane-bound compartments, including those of the secretory pathway itself. The Golgi has the capacity of processing grams of proteins per day, such as the digestive enzymes secreted by the exocrine pancreas.

Despite this enormous protein trafficking, the Golgi complex keeps its structural integrity. At the structural level, the most basic organization of the Golgi complex found in most organisms comprises three sub-compartments, the *cis*, medial, and *trans* cisternae, flattened membrane-bound compartments. In mammalian cells, they are of 1 μ m cross-sectional diameter and stacked to form a polarized compact structure, the Golgi stack (Figure 1). A noticeable exception to the stacked organization is the Golgi in *Saccharomyces cerevisiae*, which displays only single cisternae, at least in normal lab conditions (Rambourg *et al.*, 1993).

This Golgi stack is flanked on each side by a tubular membrane network: The *cis* Golgi network (CGN) at the *cis* side of the stack where proteins that have just exited the ER enter the Golgi complex, and the *trans* Golgi network (TGN), where they exit. In mammalian cells, the stacks are connected together by tubules to form the so-called mammalian Golgi ribbon capping the nucleus (Figure 1). In non-mammalian species, the Golgi stacks are not connected and remain discrete in the cytoplasm, for instance in *Drosophila* (Kondylis and Rabouille, 2009). In addition to the stack's *cis* to *trans* polarity and to the 3D ribbon organization, there is also lateral anisotropy within each cisterna: the cisterna thin core seems to be functionally different from its rims that are often dilated and highly fenestrated (Weidman *et al.*, 1993; Figure 1).

Recognized 50 years ago by Nobel Prize winner George Palade (Palade, 1975), *cis* to *trans* anterograde transport through the Golgi is a prerequisite for almost all proteins that reach the plasma membrane and the extracellular medium. There is now a consensus about the molecular machinery mediating intra-Golgi transport, as recognized by the Nobel Prize awarded to James E. Rothman in 2013, a prize that also recognized Randy W. Schekman and Thomas S. Südhof for the elucidation of the machinery required for ER exit and neurotransmitter release, respectively. However, a general agreement on how intra-Golgi transport is mechanistically sustained is yet to be reached. We are now down to six models and not closer to reach a consensus, as groups using almost identical technology continue to reach opposite conclusions.

A Crash Course in the Machinery Involved in Intra-Golgi Transport

In order to provide a framework to place the different models by which proteins are thought to undergo intra-Golgi transport, we briefly mention here a number of key molecules required in the process (reviewed in Mellman and Warren, 2000).

Figure 1 The Golgi complex. (a) Electron micrograph of a Golgi stack of a mouse epithelial fibroblast. A portion of the Golgi ribbon is displayed between brackets. NE, nuclear envelope; ER, endoplasmic reticulum. (b) Cartoon representation of a Golgi stack comprising 3 stacked cisternae (*cis*, medial, and *trans*), each with a core (center) and more dilated (and fenestrated) rims. Each cisterna is also laterally linked to an equivalent cisterna by tubular connections, thus forming the Golgi ribbon.

COPI-coated vesicles

Net forward movement of proteins through the secretory pathway is mediated by formation of small membrane carriers that specifically fuse with receptor compartments. One type that buds at the Golgi are COPI (coatamer protein complex I)-coated vesicles that were identified in the late 80s by the group of Jim Rothman (Malhotra *et al.*, 1989). COPI is a cytosolic 700-kDa protein complex comprising seven stoichiometric subunits, α , β , β' , γ , δ , ϵ , and ζ -COP conserved from yeast to mammals (Gaynor *et al.*, 1998) and preassembled into two cytoplasmic sub-complexes in the cytoplasm (β , γ , δ and ζ -COP subunits on one hand, and α , β and ϵ -COP subunits, on the second hand) (Watson *et al.*, 2004). Recruited upon activation of the activated small GTPase ADP-ribosylation factor 1 (Arf1), the coatamer complex is sufficient for COPI-coated vesicle formation (reviewed in Hsu and Yang, 2009).

Note that in addition to COPI-coated vesicles, two (and perhaps more) other types of coated vesicles are present in the secretory pathway. COPII-coated vesicles bud from the ER and form ER exit sites (reviewed in Lee and Schekman, 2004), whereas clathrin-coated vesicles bud from the TGN to mediate transport of newly synthesized lysosomal hydrolases to the lysosomes (as well as from the plasma membrane to mediate endocytosis of transmembrane receptors).

Tethers and Rabs

The fusion of small carriers to their receptor compartment requires at least two types of complexes. The first is made of tethering factors and their associated small Rab GTPases. In the Golgi, there are two types of tethers: (1) long coiled-coil peripheral proteins called golgins, except Giantin that spans the membrane, and GRASP65/55 that are not coiled-coils and (2) multimeric complexes, such as the COG (conserved oligomeric Golgi) (Lees *et al.*, 2010) and TRAPP (transport protein particle) (Hughson and Reinisch, 2010). All specifically associate to one (or more) of the 60 small Rab GTPases (reviewed in Pfeffer, 2013a; Ramirez and Lowe, 2009; Short *et al.*, 2005; Sinka *et al.*, 2008 for the golgins and GRASPs; Cottam and Ungar, 2012 for the COG; and Barrowman *et al.*, 2010 for the TRAPP).

SNARE complexes

The second complex required for the fusion of small carriers to their receptor compartment is made of SNARE complexes and their 'recycling/priming' machinery (trimeric triple ATPase NSF and its SNARE adapter SNAP). SNAREs are type II transmembrane proteins with most of their mass in the cytoplasm. They are functionally divided into v-SNAREs for the SNAREs associated with the vesicle and t-SNAREs for those at target compartments (Fasshauer *et al.*, 1998). Overlapping this

functional definition, SNAREs are also classified as Qa, Qb, Qc and R subfamilies. For intra-Golgi transport, the Qa t-SNARE is Syntaxin 5, Qb v-SNARE, Gos28, the Qc t-SNARE Gs15 and the R-tSNARE, Ykt6, that are assembled, as other SNAREs complexes in a parallel helical bundle (Malsam and Sollner, 2011; Sollner *et al.*, 1993; Sudhof and Rothman, 2009).

Upon budding, a coated vesicle incorporates a v-SNARE, a tether and a Rab. When the coat is shed, the vesicle is captured near the target membrane via the interaction of tethers at their surface and tether at the surface of the target compartment. This allows the formation of functional SNARE complexes and mediates bilayer fusion. When fusion is achieved, the SNARE complex must disassemble to recycle the SNARE molecules, and this is mediated by NSF and SNAP (for details, see excellent review by Malsam and Sollner, 2011).

The Vesicular Anterograde Transport Model

At the beginning of the 1980s, the group of Jim Rothman at Stanford University, CA, designed a biochemical assay aimed to dissect the different steps of intra-Golgi transport. The concept behind this assay was to follow the acquisition of endoglycosidase H (endoH) resistance of a sensitive VSV-G protein contained in a 'donor' Golgi fraction enriched from the mutant CHO cell line that lacks the N-acetylglucosaminyl-transferase. This fraction was mixed with an acceptor Golgi fraction from wild-type CHO cells. Vesicles derived from the donor Golgi fraction (thus encapsulating endoH sensitive VSV-G) would fuse with wild-type acceptor Golgi, allowing the VSV-G oligosaccharide chain to be processed and become endoH-resistant (Balch *et al.*, 1984; Fries and Rothman, 1980). This assay allowed the identification of key molecules, such as NSF (Malhotra *et al.*, 1988), SNAP (Clary *et al.*, 1990) and COPI (Malhotra *et al.*, 1989; Orci *et al.*, 1989; Waters *et al.*, 1991) and SNAREs (Sollner *et al.*, 1993).

Note that at the same time and only a few miles away, at the University of Berkeley, CA, the Schekman's group designed a forward genetic screen in yeast (Novick and Schekman, 1979) that identified 23 genes required for secretion, including the COPII components (Barlowe *et al.*, 1994; Novick *et al.*, 1980). Both breakthroughs rang the advent of molecular membrane traffic.

The 'vesicular anterograde transport model' was the first attempt to make sense of the molecular data obtained with the Golgi transport assay, and has paved the first roadmap of intra-Golgi transport. In this model, the 2–4 cisternae of the Golgi stack (each defined by a set of Golgi resident enzymes, such as glycosylation enzymes and proteases) are proposed to be static over the time scale of protein flow across it (typically 5–25 min, depending on the cargo). In this model, what moves is the secretory cargo. Upon delivery from the ER to the *cis*-most cisterna, the cargo undergoes a series of modifications specific to this cisterna. The cargo is then repackaged into COPI-coated vesicles that deliver it to the medial cisternae where it is further modified. It is then repackaged again in COPI-coated vesicles to reach the *trans* cisterna where it undergo final modifications before exiting the Golgi (reviewed in Rothman, 2010; Figure 2(a)).

This model is very much in line with the general consensus that small vesicular carriers are the means by which proteins

reach their destination, as it is the case for the first step of the secretory pathway, the exit of the ER by COPII-coated vesicles (Barlowe *et al.*, 1994). Furthermore, the use of vesicles as anterograde vehicles conceptually allows the Golgi to maintain its structural integrity.

The Cisternal Maturation Model

In the mid-late 1990s, however, the cisternal maturation model, that was prevalent in the pre-Rothman era (Morre *et al.*, 1979) started to reemerge as an alternative for intra-Golgi transport (Glick *et al.*, 1997). One of the motivations for challenging the vesicular transport model was the size that some of the cargo adopts, such as long algal scales (Becker *et al.*, 1995) and rod shape trimeric collagen complex of 300 nm, both way too large to fit into a 50–100 nm COPI-coated vesicles.

The cisternal maturation model has two tenets: Tenet 1 proposes that the cargo is static in one membrane compartment that undergoes changes of its identity. In this model, the part that moves is the processing machinery, not the secretory cargo. Exiting the ER, the cargo is present in a compartment at the *cis* side of the most *cis* Golgi cisterna. This compartment acquires *cis* Golgi resident enzymes and therefore becomes a *bonafide cis* cisterna. Tenet 2 proposes that the acquisition of cisternal identity is mediated by the retrograde movement of these enzymes by COPI-coated vesicles from the preexisting *cis* cisterna that becomes devoid of *cis* markers. But in the same time frame, this cisterna acquires medial markers from the preexisting medial cisterna and becomes a medial cisterna (Figure 2(b)), whereas the medial cisterna becomes a *trans* cisterna by the same retrograde movement of *trans* markers.

Overall, the features that best distinguish the two models (cisternal maturation vs. vesicular anterograde transport) are the content and directionality of the COPI-coated vesicles that bud from the rims of Golgi cisternae. In the vesicular transport model, COPI vesicles carry cargo and move from one Golgi cisterna to the next in an anterograde *cis* > medial > *trans* fashion. In the cisternal maturation model, the COPI-coated vesicles move in a retrograde *trans* > medial > *cis* fashion and function as a retrieving device that is used by Golgi enzymes to maintain their specific and differential localization over the Golgi stack (Rabouille and Klumperman, 2005).

The evidence for the cisternal maturation model is to be found in four separate sets of results:

- Large cargo, such as collagen has been shown to move through the Golgi stack without entering vesicular structures (Bonfanti *et al.*, 1998; Mironov *et al.*, 2001).
- Purified COPI-coated vesicles are shown to contain a higher concentration of Golgi enzymes/proteins than secretory cargo (Lanoix *et al.*, 1999, 2001), supporting the role of COPI vesicles in cisternal maturation (Gannon *et al.*, 2011; Gilchrist *et al.*, 2006). Conversely, abundant cargo, such as albumin appears depleted in these vesicles when compared to the Golgi stack (Gilchrist *et al.*, 2006).
- COPI-coated vesicles observed *in vivo* by immuno-electron microscopy are shown to have 1.5-fold more Mannosidase II, a medial Golgi resident enzyme, than the adjacent cisternae (Martinez-Menarguez *et al.*, 2001). Furthermore,

Figure 2 The different models by which proteins are proposed to undergo intra-Golgi transport. (a) Vesicular anterograde transport model: The Golgi stack and its resident proteins are static while the secretory cargo moves through the cisternae in a *cis* to *trans* fashion via COPI-coated vesicles. (b) Cisternal maturation model: The cargo remains in one cisterna that acquires in turn *cis*, medial and *trans* identity by the COPI-coated vesicle mediated retrograde movement of Golgi resident enzymes. (c) Bidirectional model: COPI-coated vesicles mediate the anterograde transport of cargo and the retrograde transport of Golgi enzymes. (d) Rim progression model: Large cargo is transported forward by rearrangement/budding of one cisternal rim and fusion to the next. In this model, the Golgi enzymes are proposed to remain in the cisternal core. (e) Intercisternal continuities: Vesicles are not involved in the cargo anterograde transport that is mediated by intercisternal tubular bridges. Golgi resident enzymes are also moving through the tubules as well as in COPI-coated vesicles. (f) Rapid partitioning model. The cargo is able to leave the Golgi from any cisternae after being enriched in sphingolipid domains whereas the Golgi enzymes are retained in the stack in glycerophospholipids.

GFP tagged GalNAc-Transferase 2 is shown to be present in COPI-coated vesicles identified by 3D-electron tomography after GFP-triggered DAB precipitation following illumination (Grabenbauer *et al.*, 2005).

- State of the art live cell imaging techniques in yeast has shown the conversion of a *cis* cisterna into a *trans* one as predicted by the model (Losev *et al.*, 2006; Matsuura-Tokita *et al.*, 2006).

The COPI-mediated Bidirectional Transport Model

Although many compelling evidences (listed above) have been gathered in support of cisternal maturation, the debate remained open. The 'first strategy' to support the vesicular transport model has been to get evidence that COPI-coated vesicles also contain secretory cargo (moving in an anterograde manner) in addition to Golgi enzymes (moving in a retrograde manner; Figure 2(c), tenet 2). Using the same technique of immuno-electron microscopy as the Klumperman's group (Martinez-Menarguez *et al.*, 2001), the Orci's group showed that in insulin producing cells, COPI-coated vesicles budding at every level of the Golgi stack contain both the KDEL receptor (retrograde-directed) and proinsulin (anterograde-directed) (Orci *et al.*, 1997).

The Warren's group then showed the coexistence of two classes of COPI-coated vesicles: The first class contains Golgin 84 and CASP, lacks cargo receptor of the p24 family and is enriched in Golgi enzymes. Manipulation of these golgins inhibits the delivery of Golgi enzymes to the ER, supporting the role of these first class of COPI vesicles in retrograde transport. The second class of COPI-coated vesicles contains p115 and giantin, and uses GM130 and Rab1 to be tethered to the CGN in an anterograde manner (Malsam *et al.*, 2005). These results suggest that COPI-coated vesicles can mediate the differential retrograde and anterograde movement of two different types of molecules, whether this is related to the existence of multiple coatomer complexes isolated by the group F. Wieland (Wegmann *et al.*, 2004) remains to be established.

Recently, a study aiming to monitor Golgi transport by live cell imaging in mammalian cells supported the ability of COPI-coated vesicles to move both secretory cargo and Golgi resident enzymes. This study uses fused cells containing two types of Golgi, one marked by a small secretory cargo coupled to a fluorophore and the other marked by a Golgi resident enzyme coupled to a different fluorophore. Both cargo and Golgi enzymes are transported in small carriers with properties consistent with COPI-coated vesicles, suggesting that these vesicles have the ability to incorporate both types of molecules (Pellett *et al.*, 2013). However, this assay monitors material exchange between two Golgis (inter-Golgi), not intra-Golgi transport. It is therefore possible that COPI delivers cargo (and Golgi enzymes) from one given cisterna in one Golgi to an equivalent cisterna in the second Golgi. It does not directly address how cargo progresses through the stack.

In summary, COPI-coated vesicles may contain anterograde cargo as well as Golgi enzymes, and they might mediate anterograde as well as retrograde transport.

The 'second strategy' to support the vesicular transport model has been to directly test and disprove one critical prediction of the cisternal maturation model, according to which,

once a cargo is trapped in a given Golgi cisterna, it progresses forward without leaving this cisterna (tenet 1). The group of Rothman at Yale developed a new method (Lavieau *et al.*, 2013) exactly designed to follow forward movement of cargo of different size within the Golgi stack. The first cargo used in this study is a chimeric type I membrane protein made of CD8 fused to 4 copies of the dimerization motif FM at its N-terminal luminal domain (4FM-CD8). The presence of these FM domains makes this protein to spontaneously self-oligomerize. Conversely, addition to a specific small molecule (AP21998) triggers the release of monomers (Rollins *et al.*, 2000). When expressed in any compartments of the secretory pathway, the self-aggregated protein is trapped. For instance in the ER, it forms small aggregates (staples) that spans and compacts the width of the ER tubules, as if 'stapled.'

By manipulating the culture conditions in the presence and absence of the disaggregating drug, staples were allowed to form either in the *cis* or in the *trans* cisternae of the Golgi stack. Once formed, for instance in the *cis* cisterna, the staples were found not to move, and therefore did not traverse the Golgi stack. As controls, monomeric 4FM-CD8 moved to the cell surface (Lavieau *et al.*, 2013). The fact that 4FM-CD8 staples remain where they are generated supports a model in which Golgi compartments are static.

Staple technology has nevertheless limitations that are subjected to interpretation. Indeed, A. Luini's group (Napoli, Italy) used an almost identical staple strategy and reached opposite results (Rizzo *et al.*, 2013). In this study, instead of 4FM-CD8 (see above), the type II protein Golgi mannosidase I was appended by 3 FM domains at the C-terminal (MannI-3FM). Again it self-aggregates and forms plaques in the *cis* Golgi cisterna as expected, but the main difference is that these plaques are later found in the *trans* cisterna. This suggests that they have moved forward, contrary to the 4FM-CD8 staples, but in agreement with the prediction of the cisternal maturation model.

Whether the sharp difference in these results arises from using a cargo (CD8) instead of a resident enzyme (MannI), a type I instead of the type II protein, 3 FM domains instead of 4, at high or low expression, is not elucidated, and we are left with no clearer answers (Morriswood and Warren, 2013).

The Rim Progression Model Specifically Addresses Large Cargo Transport

As mentioned above, the original motivation to challenge the vesicular anterograde transport model was that large cargo could not fit into the small 50–70 nm COPI-coated vesicles. So, the 'third strategy' to validate this model was to explain how large cargo moves from cisterna to cisterna across the Golgi stack. The existence of mega vesicles moving large cargo forward (Volchuk *et al.*, 2000) has recently been reinvestigated using the staple technology (see above). Indeed, large aggregates of a cargo can be generated, but this time with the distinct difference that these aggregates are not attached to the Golgi membrane by a transmembrane domain as in the case of 4FM-CD8 (Lavieau *et al.*, 2013). Remarkably, these aggregates move through the Golgi stacks through cisternal rims. This has led to the so-called 'Rim progression model' that proposes that large cargo are enriched at the cisternal rims and that the rims

progress forward by rearrangement/budding from one cisterna and fusion to the next, very much alike what is proposed for COPI vesicles enriched in small cargo (that is independently packaged) (Figure 2(d)).

There are, however, two major difference with the COPI-coated vesicles. The fission of COPI-coated vesicles is well documented and largely depends on the coat itself (Adolf *et al.*, 2013), whereas nothing is known on the fission of these rim-derived mega vesicles. Second, it appears that a Golgi ribbon is necessary for the intra-Golgi transport of large cargo. When the mammalian Golgi ribbon is broken into ministacks, the transport of large cargo is significantly slowed down whereas small cargo (such as VSV-G) is unaffected (Lavieu *et al.*, 2014). This suggests that large vesicles generated from one cisterna in one given Golgi stack cannot fuse with the next cisterna of the same stack (see below VI for a possible mechanism).

The rim progression model also proposes that Golgi resident enzymes are enriched in the cisternal core (Cosson *et al.*, 2002) and that they do not diffuse to the rims. How the Golgi enzymes are retained in the cisterna core in a manner that also allows their dynamic incorporation in COPI-coated vesicles for recycling to the ER but not their diffusion in the rims remains to be investigated. In this regard, the kin-oligomerisation model proposed by the Warren's group (Nilsson *et al.*, 1994) could be useful in explaining both the retention/localization and the dynamics of Golgi resident enzymes. The stalks and transmembrane domains of Golgi enzymes localizing in the same set of cisternae have been shown to form oligomers (kin-oligomer), helping in their retention. Modulation of the size of this oligomer (through mechanisms that are still to be defined) could allow the enzyme recycling to the ER (between 5% and 10%) via COPI-coated vesicles.

The Cisternal Progenitor Model

How can rims participate in forward movement large cargo and more generally of secretory cargo?

The first consideration put forward by the Pfefer' group (Pfeffer, 2013a) is that in mammalian cells, the rims are very dynamics and the site of many lateral fusion/fission events. For instance, the depolymerization of microtubules, the depletion of Golgin 84 (Diao *et al.*, 2003), and the double depletion of GRASP65 and 55 (Jarvela and Linstedt, 2014) leads to the dispersion of Golgi ribbon in ministacks. Second, it is now well established from research in the endocytic field that transport vectoriality is provided by small Rab GTPases. They decorate the surfaces of almost all membrane compartments (including the Golgi) where they catalyze the formation of membrane microdomains (particularly clear on the endosomal system (Sonnichsen *et al.*, 2000). The vectoriality is provided by Rab cascade of Rab activation by specific guanine nucleotide exchange factors (GEFs) and inactivation by specific GTPase-activating proteins (GAPs) (Chesneau *et al.*, 2012; Pfeffer, 2013b; Poteryaev *et al.*, 2010; Rink *et al.*, 2005; Rivera-Molina and Novick, 2009).

Applied to the Golgi, this Rab cascade has led to the following model: A Golgi stack comprises three tightly stacked cisternae. The *cis* cisterna is marked by RabA, the medial by RabB, and the *trans* by RabC. RabA defines a domain

containing the machinery facilitating homologous fusion between RabA containing cisterna. RabB and RabC would have the same property for the medial and *trans* cisterna. This would account for, for instance, the fusion of ministacks into a Golgi ribbon. RabA can also recruit the GEF for RabB. As a result, a RabA domain leads to the formation of an adjacent RabB domain but because of the ministack dynamics, the two domains could be separated. This new RabB compartment deriving for the *cis* cisterna can then fuse with the compartment in which RabB is the most enriched, the medial cisterna. If this new RabB compartment is a rim enriched with large cargo, it would essentially equate with the fusion of the *cis* cisterna's rim with the medial cisterna, exactly what the rim progression proposes.

At the same time, RabB could recruit the GEF for RabC and the same scenario could repeat itself so that a new RabC compartment deriving from the medial cisterna would fuse with the *trans* cisterna (Pfeffer, 2013b). In conclusion, one or several Rab cascades could in principle explain the forward progression of the cisternal rims. It would also explain why a Golgi ribbon is conducive for rim progression and (see above).

In conclusion, many evidences have been gathered to support either the cisternal maturation model or the vesicular anterograde transport model in its extended version that includes rim progression. As stated above, the issue is, however, not settled and is further complicated by the description of two new models.

Intercisternal Continuities. Is COPI No Longer Involved?

At the beginning of the new century, in what seemed a complete departure from the involvement of COPI-coated vesicle in intra-Golgi transport, a new model emerged. This was based on observations of intercisternal bridges that seemed to form under high cargo loading, such as VSV-G transfection of HeLa cells (Trucco *et al.*, 2004) or glucose stimulation of pancreatic islets (Marsh *et al.*, 2004). Till this time, the Golgi cisternae were considered to be discrete sub-compartments of the Golgi stack, and although each cisterna is linked laterally to an equivalent adjacent cisterna to form the Golgi ribbon (at least in mammalian cells, see Figure 1), intercisternal bridges were not readily (to almost never) observed.

This lack of evidence might be due to the fact that these bridges cannot be resolved by light microscopy. Furthermore, due to their small size and tubular nature, they would mostly be missed in EM using ultrathin sections. In this regard, 3D-electron tomography and its application on cellular structures provided the first evidence for their existence. In the pancreatic islet, few T-shaped tubules are found to connect the flat core part of two cisternae (Marsh *et al.*, 2004). In VSV-G expressing HeLa cells, the tubules are reported to be more numerous and tended to preferentially connect the rims (Trucco *et al.*, 2004).

The relevance of these tubules has become topical to Golgi transport as they are shown to play a role during intra-Golgi trafficking of several secretory cargo (Figure 2(e)). This would therefore suggest that COPI-coated vesicles are no longer involved in transport. Indeed, intra-Golgi tubulation (as well inter-Golgi tubulation generating the Golgi ribbon) appears to be induced by the enzyme cPLA2 (San Pietro *et al.*, 2009).

cPLA2 inhibition prevents both types of Golgi tubulation and results in the inhibition of anterograde transport (San Pietro *et al.*, 2009). A recent article from the same group now reports that albumin uses these intercisternal continuities for its secretion, but not pro-collagen, suggesting that multiple types of transport might occur in the same stack (Beznoussenko *et al.*, 2014). Golgi enzymes also seem to also move from cisterna to cisterna via these tubules (Yang *et al.*, 2011).

Is the COPI coat out of the equation with the involvement of intercisternal continuities in intra-Golgi transport? A membrane bud coated with COPI is meant to become a COPI-coated vesicle but under certain circumstances, it can also become an intercisternal tubule. This bud fate decision is mediated by the interplay between two enzymes. When lyso-phosphatidic acid (LPA) acyltransferase type γ (LPAAT- γ) that promotes COPI-coated vesicle formation is inhibited, tubules grow. cPLA2 inhibits LPAAT- γ , thus promoting tubule growth at the expense of vesicles. As expected, the COPI complex is necessary for the formation of the vesicles (that according to the authors carry Golgi enzymes in the retrograde fashion), but unexpectedly, also the tubules through which small secretory cargo and enzymes move (Yang *et al.*, 2011).

In conclusion, the role for COPI vesicles in anterograde is put under scrutiny but not the role of the COPI coat itself that is here shown to be instrumental in the formation of intercisternal continuities.

The Rapid Partitioning Model

The last model described here has been put forward in 2008 by the group of J. Lippincott-Schwartz (NIH, Bethesda) (Patterson *et al.*, 2008). This group studied the dynamics of small secretory cargo (VSV-G-GFP) through the secretory pathway and got results that did not fit the cisternal maturation model. This model predicts that once a cargo enters the Golgi, it would remain in this organelle a given time to allow the maturation to take place, and leave the Golgi at the TGN with a linear kinetics, in line with the consumption of a single compartment. Instead, the Lippincott-Schwartz's group found no lag time and an exponential kinetics. From this, they concluded that a cargo is able to leave the Golgi from any cisterna, not only from the TGN. Their second observation was that Golgi resident enzymes and cargo did not completely overlap within a single Golgi cisterna, suggesting the existence of domains within cisternae.

In an attempt to integrate the kinetic data mentioned above and the existence of these two domains, lipid-trafficking pathways were introduced as the driving force for protein trafficking. The Golgi contains two major lipids, the glycerophospholipids (GPLs) and sphingolipids (SLs) that have significantly different synthetic and trafficking routes. On one hand, GPLs are synthesized in the ER and are transported to the Golgi in vesicles together with proteins. On the other hand, SLs are uniquely synthesized in the Golgi (Levine *et al.*, 2000; van Meer *et al.*, 2008) from ceramide that is itself produced in the ER but transferred directly to the trans Golgi by a lipid carrier protein, CERT (D'Angelo *et al.*, 2007; Halter *et al.*, 2007).

The rapid partitioning model proposes that each cisterna (whether *cis*, medial or *trans*) contains two domains: The first is enriched in SLs, and a large proportion of secretory cargo (that has a higher affinity for this lipid) partitions in this

domain. This is consistent with observations that SLs are delivered to the PM from the Golgi by transport carriers that are formed at all levels of the Golgi (Helms and Zurzolo, 2004; Rodriguez-Boulán *et al.*, 2005; van Meer *et al.*, 2008) and preferably at the rims. The second domain is enriched in GPLs in which Golgi processing enzymes (that have a higher affinity for this lipid) partition. This has been proposed to be part of the localization/retention of glycosylation enzymes within the Golgi by S. Munro's group (Bretscher and Munro, 1993).

Thus, a SM-rich domain containing the partitioned cargo could be incorporated in transport carriers, the nature of which needs to be determined. Concomitantly, the glycosylation enzymes would be retained in the GLM domain of the Golgi, thus both retained and retrieved back to the ER- in GLM-rich carriers (Figure 2(f)), possibly in COPI-coated vesicles.

How mechanisms of Golgi enzyme retention in the Golgi that have been proposed in the past (Nilsson *et al.*, 1994; Opat *et al.*, 2001; Schmitz *et al.*, 2008; Tu *et al.*, 2008) fit in the rapid partitioning is, however, not addressed. For instance, could kin-oligomerisation of Golgi enzymes (see above, Nilsson *et al.*, 1994) be modulated by GLM?

Conclusions/perspectives

The journey ends here with an entire library of evidences in support of each model, ranging from live cell imaging to EM to 3D-electron tomography, transport assays, biochemical assays, mathematical modeling, and mass spectrometry, in yeast and several mammalian cells. In 2009, the community agrees to disagree in an amiable fashion (Emr *et al.*, 2009).

Whether this reflects fundamental biological differences in cargo types, cell types, growth conditions, tissue-cultured conditions versus *in vivo*, is starting to be addressed. In particular, the departure from VSV-G as a typical anterograde secretory cargo has been initiated, for instance in the flow cytometry-based assay for measuring constitutive secretion from the Peden' lab (Gordon *et al.*, 2010), and the RUSH system from the Perez's lab (Boncompain *et al.*, 2012). The latter allows controlled studies of different cargo molecule trafficking and might reveal interesting differences that might reconcile aspects of the proposed models. The next step will be to study intra-Golgi transport *in vivo* with endogenous proteins tagged in the genome.

Post-Golgi Transport – Cargo, Carriers, and Pathways

JL Stow, The University of Queensland, Brisbane, QLD, Australia

Introduction

The bulk of newly synthesized proteins transported through the secretory pathway, having traversed the endoplasmic reticulum (ER) and Golgi complex, will arrive at the trans-Golgi network (TGN) where they will be directed into one or more post-Golgi pathways, *en route* to their final destinations. Upon leaving the neat confines of the Golgi complex, this protein cargo will find itself in the labyrinthine world of post-Golgi transport pathways, where carriers of different guises move cargo along criss-crossing routes to endosomal hubs, to other organelles, or to the various domains of the plasma membrane for residence or release.

The cargo of newly synthesized proteins moving through the ER, COPII vesicles, and the Golgi cisternae is concentrated and moving mostly in the same direction, making it possible to label and experimentally track cargo molecules through the early secretory pathway in cells (Farquhar and Palade, 1998). Some cells then have large distinctive secretory granules for the later stages of transport where the cargo is also concentrated. However, the bulk of transport beyond the TGN occurs in many fast-moving, transient carriers where the cargo is dilute and in small volumes. Thus the carriers and cargo of these constitutive transport pathways have traditionally been much more difficult to trace and study, especially since these pathways are often varied and customized in different cell types.

With the advent of GFP-tagged proteins and the ability to image trafficking in live cells and model organisms (Lippincott-Schwartz *et al.*, 2000), together with genomics and proteomics, there is growing understanding of the TGN and of post-Golgi transport. Increasingly we learn from the defective trafficking that results from gene mutations – experimentally introduced mutations and those in model organisms and in human disease (De Matteis and Luini, 2011). The molecular machinery of the TGN and its carriers, at the ‘business end’ of the secretory pathway – close to the functional sites of proteins, can offer unique opportunities for experimental or clinical modulation of protein transport and function.

Overview of Pathways

TGN-Derived Constitutive Transport

The TGN is an active transport hub positioned at the trans-side of the Golgi stack. Ultrastructurally it is distinguished as a large pleiomorphic reticulum with multiple budding profiles of clathrin- and non-clathrin-coated vesicles (Farquhar and Palade, 1998). The morphology of vesicles, coats, and relationship between the TGN and Golgi cisternae have been further revealed through elegant high voltage electron tomographic studies (Mogelsvang *et al.*, 2004; Storrie *et al.*, 2012). Imaging in living (unfixed) cells has revealed that the TGN

also gives rise to many dynamic tubular extensions coursing along microtubules (De Matteis and Luini, 2008; Goud and Gleeson, 2010). The TGN is positioned close to the microtubule-organizing center and it has associated actin arrays. From early on (Farquhar and Palade, 1998), close connections between the TGN and ER were noted, which may serve in lipid transfer (Ngo and Ridgway, 2009).

In all eukaryotic cells there is constitutive (continuous) transport of newly synthesized and sometimes recycling proteins from the TGN to the cell surface and multiple other destinations. Cargo transport through these pathways typically involves the continuous movement of small amounts of cargo in carriers that form through budding at the TGN and then fuse with their target membrane upon cargo delivery. Multiple types of carriers and transport routes are needed for constitutive transport (Figure 1). These pathways service major cell functions such as secretion, receptor recycling and signaling, cell adhesion, cell movement, and cell proliferation. The post-Golgi pathways feed into endosomal hubs, autophagic organelles, and also serve for retrograde transport. The variety of cargo and the volume of constitutive transport performed in different cell types can vary enormously. Minimal transport is needed, for instance, at a maintenance level in mature parenchymal cells, which may be just replenishing their own membranes and organelles. At the other extreme, protein synthesis and constitutive trafficking in mature plasma cells can be almost solely dedicated to the secretion of large amounts of immunoglobulin. Indeed, for this reason, this was one of the first secretory pathways where the role of the Golgi complex was first revealed (Zagury *et al.*, 1970).

In some endo- and exocrine cell types there are additional pathways for the regulated secretion of special cell products. These pathways differ from constitutive transport in several ways, namely that cargo leaving the TGN is packaged and stored in large granules or lysosome-related organelles (LROs) for release in response to specific stimuli. Regulated secretion is described elsewhere. The details of constitutive trafficking are worthy of further consideration here.

Modulating Constitutive Transport

The level of constitutive transport can be ‘dialed up’ to cope with periods of high demand for secretion or for stimulus-coupled translocation of proteins to the cell surface. This is exemplified in macrophages, which, upon activation by pathogen contact, synthesize and secrete inflammatory cytokines. To accommodate this sudden need for cytokine release, the expression of trafficking machinery is increased and the number of constitutive carriers budding off the TGN is enhanced (Lieu *et al.*, 2008; Stow and Murray, 2013). The levels of secretion of inflammatory mediators in macrophages and epithelial cells can also be modulated by siphoning off cargo from the Golgi into autophagy-related organelles (Narita *et al.*,

Figure 1 Transport in polarized cells. Polarity is a permanent feature of differentiated epithelial cells and neurons; cells undergoing migration or lymphocytes forming an immunological synapse with a target cell have contextual polarity. In all cases the TGN has the added complication of having to direct different cargo and carriers to the basolateral pole or the apical pole of epithelial cells, the dendrites or axon of neurons, the front or back of migrating cells, and the synapse or rest of cell surface in lymphocytes. Sorting, carriers, and routes for polarized transport are described herein.

2011). Another example of up-regulated trafficking is in adipocytes, which, upon activation of the insulin receptor, must translocate Glut4 glucose transporters to the cell surface from a 'holding pattern' in special post-Golgi vesicles (Stockli *et al.*, 2011). These and other situations demonstrate that constitutive trafficking in post-Golgi pathways can be modulated and tailored to the needs of the cell.

Polarized Transport

Transport from the TGN to the cell surface instantly takes on a new level of complexity in cells where distinct cargo has to be routed in different directions for delivery to separate cell domains (Mellman and Nelson, 2008; Figure 1). Mature epithelial cells and neurons are classical examples of differentiated, polarized cell types with morphologically and functionally different poles. Cell polarity can also be temporary or contextual, for instance, in migrating cells which develop a leading edge for forward movement (Miller *et al.*, 2009; Veale *et al.*, 2010), and in lymphocytes that come into contact with a target cell at specialized contact zones or immunological synapses (Angus and Griffiths, 2013). In all of these cases, the cells must have the ability to direct a subset of cargo toward a particular 'end' or 'side' of the cell (Figure 1).

Both the TGN and endosomes are sorting stations for polarized trafficking and at these sites a number of mechanisms are used to sort cargo into carriers destined for different polarized domains (Apodaca *et al.*, 2012; Weisz and Rodriguez-Boulan, 2009). As described below, lipid-based sorting and carriers often service apical transport in epithelia, while protein-based sorting, including sorting signals, specific adapters, and both clathrin- and non-clathrin-mediated carriers service basolateral transport.

The cytoskeleton – both microtubule and actin networks – plays ubiquitous roles in TGN function and in all pathways of post-Golgi transport (Goud and Gleeson, 2010). However, microtubules have very demonstrable roles in directing carriers to specific surface domains in polarized cells (Musch, 2004). In both permanent and contextual cell polarity, microtubules and microtubule motors offer very directed transport to

specific membrane domains. This can be seen in cytotoxic T cells where, upon forming an immunological synapse with a target cell, the Golgi complex and TGN rotate to face this contact zone and interconnecting microtubules directly carry secretory vesicles and LROs to this highly specific polarized site for cell–cell killing (Angus and Griffiths, 2013). Similarly, cilia emerging from the apical surface of epithelial cells have a special post-Golgi transport loop directed by microtubules to shuttle cargo to the base of the cilia for their formation and function (Deretic, 2013).

Constitutive Transport via Endosomal Hubs

While constitutive traffic was originally conceived as solely direct transport from the TGN to the cell surface, it is now recognized that many post-Golgi pathways intersect with endosomes, especially recycling endosomes – as intervening hubs on the way to the cell surface or other destinations (Hsu and Prekeris, 2010; Figure 2). Recycling endosomes have a rich panoply of trafficking GTPases and their effectors which include scaffolds, motors, and kinases, for trafficking through this compartment. While there are multiple recycling endosome-associated Rabs, the Rab11 subfamily (11a, 11b, and 25) and Rabs8 (8a and 8b) have been widely implicated in traffic in and out of recycling endosomes (Apodaca *et al.*, 2012; Baetz and Goldenring, 2013; Hsu and Prekeris, 2010).

Recycling endosomes themselves can form a large, dynamic tubular reticulum wherein recycling surface receptors and other proteins converge with newly synthesized exocytic cargo arriving from the TGN. Proteins can also be directed in retrograde fashion from endosomal hubs back to the TGN. Hubs may be required in exocytic pathways to perform additional sorting or rearrangement of cargo and to manage the timing and direction of final cargo deployment. For instance, the recycling endosome is a key hub for further cargo sorting for polarized transport in epithelial cells; basolaterally directed proteins first transit the recycling endosome after leaving the TGN (Ang *et al.*, 2004; Lock and Stow, 2005) and in 3-dimensional epithelial cysts, recycling endosomes and their

Figure 2 Routes, cargo, and carriers. The TGN gives rise to transport routes (arrows) that connect to different organelles and the cell surface. Examples 1–4 illustrate the types of cargo and TGN-derived carriers moving along some of these routes: (1) AP-1/GGA and clathrin-coated vesicles transport lysosomal hydrolases to late endosomes (Rouille *et al.*, 2000). (2) Rab6 and myosinII-associated tubular carriers undergo fission from the TGN to transport the experimental cargo protein VSV-G from TGN to recycling endosomes (Miserey-Lenkei *et al.*, 2010). (3) Tubular carriers decorated with golgin-245, syntaxin6, and Vti1b form at the TGN to transport the cytokine TNF to recycling endosomes which then carry the cytokine to the surface for release (Manderson *et al.*, 2007; Murray *et al.*, 2005). (4) The so-called ‘CART’ carriers transport selective cargo including pancreatic adenocarcinoma up-regulated factor, but not VSVG or collagen, from TGN to cell surface. CARTs use PKD for fission and are decorated with Rab6, Rab8, and myosin II (Wakana *et al.*, 2012).

machinery have primary roles in establishing luminal and basolateral cell domains (Apodaca *et al.*, 2012). In macrophages, characterization of the soluble NSF attachment protein receptor (SNARE) machinery showed that the transmembrane precursor of the cytokine TNF is trafficked from the TGN to recycling endosomes which perform the final step of delivering TNF to a polarized site on the cell surface at the outer edge of phagosomes (Murray *et al.*, 2005). Furthermore, in a variation of sorting roles, TNF may be retained at the recycling endosome by AP-1 and clathrin complexes and then trafficked in carriers with AP-1 alone to reach the cell surface (Braun *et al.*, 2007). Thus the TGN can work intimately with other organelles for multistage transport.

Cargo Sorting and Packaging at the TGN

A complex array of cargo, including soluble and transmembrane proteins, arrive at the TGN for sorting and packaging into different carriers. Multiple mechanisms are used for cargo sorting in this location, including protein-based sorting for proteins that extend into or are connected to the cytoplasm, or alternatively there are lipid-based sorting mechanisms. Protein clustering with special packaging proteins is also utilized in some cells to direct cargo into granules. The extension of TGN-derived tubules also facilitates the spatial segregation of cargo for sorting. It is clear that cargo – both proteins and lipids – along with membrane subdomains, can be separated with

high fidelity for packaging into a variety of different carriers for transport to different destinations (Figure 2).

Lipid Rafts in Sorting and Transport

Membrane lipids are also important determinants of membrane trafficking in post-Golgi pathways. The concept of glycosphingolipid and protein-rich domains, the so-called ‘lipid rafts,’ as islands in the fluid mosaic environment of biological membranes, is now embedded as a fundamental principle for clustering and organizing groups of proteins for function (e.g., receptor-mediated signaling) and for transport (Lingwood and Simons, 2010). Lipid rafts are recognized as dynamic, mobile, domains of varying sizes with a high intrinsic concentration of cholesterol and sphingolipids, which attract lipophilic proteins such as glycosylphosphatidyl-inositol (GPI)-anchored proteins, along with receptors, and molecules for signaling and cytoskeletal attachment (Lingwood and Simons, 2010; Surma *et al.*, 2012). At the TGN, lipid rafts form with the purpose of clustering specific cargo, such as GPI-anchored proteins, which cannot access protein-based sorting mechanisms on the cytoplasmic leaflet of membranes. These GPI-anchored proteins are delivered to specific destinations, most notably the apical surface of polarized cells or the bud plasma membrane of the yeast, *Saccharomyces cerevisiae*. The apical membrane of polarized epithelial cells is relatively enriched in glycosphingolipids and cholesterol compared to the basolateral membrane. Lipid rafts, from early on, were thus recognized for their role in delivering GPI-anchored proteins, some viral proteins and other cargo to the apical membrane, either through direct transport routes, or via endosomes (reviewed in Weisz and Rodriguez-Boulton, 2009). Lipid rafts not only help sort cargo but also actively help to form the carriers for such transport. Isolating populations of post-Golgi vesicles in yeast with different profiles of cholesterol or sphingolipids helped to establish that the TGN can actually sort membrane lipids to form different carriers (Klemm *et al.*, 2009). Budding of such carriers involves the coalescence of individual rafts into larger patches or domains, which create biophysical forces, including line tension (Baumgart *et al.*, 2003), which favor membrane curvature and budding of lipid raft-rich vesicles or tubules as cargo carriers (Julicher and Lipowsky, 1993; Roux *et al.*, 2005; van Meer and Vaz, 2005). The influenza proteins hemagglutinin and neuraminidase are both raft-associated proteins and the apical transport of both proteins is accelerated when they are coexpressed due to clustering of disparate rafts (Ohkura *et al.*, 2014).

Lipid rafts participate not only in sorting cargo for transport, but also in clustering the protein machinery that is important for trafficking and secretion, including elements such as SNAREs, Rabs, adapters, and cytoskeletal linkers (Weisz and Rodriguez-Boulton, 2009). The adaptor annexin II is commonly found in rafts and is required for apical transport in polarized epithelial cells (Jacob *et al.*, 2004). The secretion of the cytokine TNF in macrophages (Kay *et al.*, 2006) and of mast cell mediators (Puri and Roche, 2006) depend on lipid rafts to orchestrate the plasma membrane SNAREs, syntaxin 4, and SNAP23, for membrane fusion at the cell surface. Pathogens make ready use of lipid rafts for trafficking during cell

entry and exit (Manes *et al.*, 2003), including targeting some of the raft-associated trafficking machinery with pathogen-derived effectors. Thus membrane lipids are intimately involved in sorting, and in the differential packaging and movement of cargo in bidirectional transport between the TGN and cell surface.

Protein-Based Sorting in the TGN

Multiple mechanisms and a vast array of cytoplasmic proteins are used to sort cargo based on contact with the cytoplasmic tails of transmembrane proteins. These sorting mechanisms package cargo into a variety of vesicular and tubular carriers, although how specificity is achieved is not fully understood for all types of intrinsic cargo, given that many studies to date have used model systems or exogenous cargo. Various aspects of protein-based sorting are considered as follows.

Sorting signals

One common principle for sorting transmembrane proteins is through sorting signals encoded in the cytoplasmic tails of cargo proteins. These amino acid motifs are recognized by cytoplasmic adaptors and coat proteins to sort this cargo into specific carriers. At the TGN, tyrosine- or dileucine-based sorting signals are known for trafficking proteins to endosomes or to the basolateral domain of epithelial cells (Rodríguez-Boulán *et al.*, 2005). Protein phosphorylation and ubiquitination can also direct trafficking, and luminal O-glycosylation can act as an apical sorting signal (Scott *et al.*, 2004; Yeaman *et al.*, 1997).

Phosphatidylinositol 4-phosphate and ADP-ribosylation factors

The TGN membrane is enriched in phosphatidylinositol 4-phosphate (PI4P), which forms the basis for recruiting some of the budding machinery (as PI4P effectors) and for deforming the membranes for budding itself (De Matteis and Luini, 2008). The PI4-kinases (Pik1p in yeast or PI4KIII β in mammals) are also located on the TGN to produce PI4P for trafficking, and loss or mutation of PI4-kinases on the TGN blocks secretion of PI4P effectors usually bound to PI4P, in addition to binding one or more of the GTPases on the TGN membrane (reviewed in Santiago-Tirado and Bretscher, 2011).

One of the first proteins recruited to PI4P is the small GTPase ADP-ribosylation factor 1 (ARF1), activated on the TGN by one of its TGN-resident ARF-GEFs, Sec7 in yeast or BIG1/2 in mammals (Casanova, 2007; Jones *et al.*, 2005; Lowery *et al.*, 2013). Parenthetically, the ARF-GEFs are recruited with help from ARF and ARL (another GTPase) on the TGN (Christis and Munro, 2012; Richardson *et al.*, 2012). Thus ARFs on the TGN work in one of the striking examples of GTPase cascades that operate on several membranes throughout the cell (Mizuno-Yamasaki *et al.*, 2012). The coupling of cargo with PI4P and ARF1 forms the 'first layer' of sorting and packaging, underpinning the recruitment of adaptor complexes for multiple types of carriers assembling on the TGN.

Adaptors and clathrin-coats on the TGN

PI4P and ARF1 complexes on the TGN recruit specific sets of adaptors, the GGAs and AP-1 together with clathrin for formation of clathrin-coated vesicles (CCVs) around clustered sorting signal-selected cargo for transport to endosomes or other destinations. In yeast the Gg2 protein also recruits the PI4P kinase Pik1p to produce more local PI4P, in a positive feedback loop that is needed to support secretion (Daboussi *et al.*, 2012). The clathrin adaptor AP-1 on the TGN emulates the formation of CCV supported by AP-2 at the plasma membrane, and AP-4 is also located on the TGN although it has not yet been shown to form CCVs (Robinson, 2004). It is not clear in all cells whether GGAs and AP-1 assemble on separate or overlapping CCVs, nor ultimately how many different types of CCVs are generated.

One of the best known roles for CCVs at the TGN is in the transport of lysosomal contents to one or more stages of the endolysosomal pathway (Saftig and Klumperman, 2009). Classically, lysosomal enzymes tagged with mannose-6-phosphate (M6P) are bound by M6P receptors in the TGN, loaded into CCV, and delivered to late endosomes *en route* to lysosomes (Ghosh *et al.*, 2003). Transport of lysosomal enzymes through endosomal compartments can invoke both AP-1 and AP-3 mediated steps (Peden *et al.*, 2004). Interestingly, other components of lysosomes can be carried via different endosomal, or even direct trajectories, from the TGN to lysosomes in CCV or in non-clathrin-mediated carriers (Saftig and Klumperman, 2009). Thus, sphingosin activator protein is carried by the multipurpose receptor sortilin into CCV for transport directly from the TGN to lysosomes, bypassing M6P receptors (Lefrançois *et al.*, 2003). The enzyme, β -glucocerebrosidase, also bypasses M6P receptors, instead being carried to lysosomes with the lysosomal integral protein, LIMP-2 (Reczek *et al.*, 2007). The dire consequences of disrupting these transport steps through gene mutation or loss-of-function are evident in resulting lysosomal storage diseases (Parkinson-Lawrence *et al.*, 2010; Saftig and Klumperman, 2009).

The clathrin adaptors also participate directly in sorting for polarized transport. This was highlighted after AP-1B was discovered as an epithelial specific AP-1 isoform required for basolateral targeting (Traub and Apodaca, 2003). Genetic ablation of an AP-1B subunit in mice results in intestinal epithelial hyperplasia and loss of cell polarity (Hase *et al.*, 2013). It is now evident that AP-1B normally acts at the level of recycling endosomes, rather than in the TGN, for basolateral sorting (Ang *et al.*, 2004), but it works in concert with the ubiquitous AP-1A at the TGN for fully efficient basolateral transport (Gravotta *et al.*, 2012).

Ca²⁺-dependent sorting and transport at the TGN

The cytoplasmic actin-modeling proteins ADF/cofilin or their homologs in flies, are recruited to the TGN where they are required for sorting a subset of cargo in concert with actin and the Ca²⁺ transporter, SPCA1 (von Blume *et al.*, 2011). SPCA1 regulates Ca²⁺ influx into the TGN. The cargo sorted in this manner include specific subsets of Ca²⁺ binding and non-binding proteins. The sorting mechanism proposed involves the severing of actin filaments to release or activate SPCA1 for Ca²⁺ pumping to create local ionic environments for sorting cargo in the TGN lumen.

Tubules and Carriers – Assembly and Fission

Ultrastructural studies have shown an abundance of CCVs, COP-coated vesicles, and uncoated vesicles associated with the TGN and as budding profiles on these membranes (Farquhar and Palade, 1998; Mogelsvang *et al.*, 2004; Storrie *et al.*, 2012). In addition to vesicles, long tubular carriers have also been evident since live imaging of fluorescently tagged components has been possible (Lippincott-Schwartz *et al.*, 2000). Tubules can be seen emerging from the TGN, undergoing fission and microtubule-directed transport, and they can be selectively loaded with soluble or membrane-bound cargo (De Matteis and Luini, 2008; Goud and Gleeson, 2010; Manderson *et al.*, 2007; Miserey-Lenkei *et al.*, 2010). How many types of tubular carriers are there is not known, nor yet is the full complement of proteins engaged in sorting cargo into them, or controlling their fission and transport.

Golgins

Coiled-coil membrane tethers or scaffolds abound across the Golgi stack and TGN. On the TGN, the GRIP-golgin family members golgin-245, golgin-97, GCC185, and GCC88 act as multifunctional scaffolds for carrier formation and retrieval and for tethering organelles and protein complexes for trafficking (Goud and Gleeson, 2010). GRIP-golgins are recruited and bound to the TGN membrane via their GRIP domain and often, but not always, by interaction with members of the Arf-like ARL and the Rab families of GTPases (Goud and Gleeson, 2010). Notably, individual golgins usually occupy different subdomains of the TGN and they selectively participate in trafficking of different cargo. GTPase ARF-related protein 1 (ARFRP1) regulates the recruitment of ARL1 and golgin-245 to the TGN. Liver-specific knockout of ARFRP1 in mice interferes with the secretion of IGF1 but not IGFBP2 from hepatocytes and also disrupts sorting of Glut2 (Hesse *et al.*, 2012), indicative of a role for golgin-245 in the transport of only a subset of hepatocyte cargo. In macrophages, golgin-245 transports TNF out of the TGN for secretion (Lieu *et al.*, 2008). Golgin-97 transports E-cadherin out of the TGN in epithelial cells (Lock and Stow, 2005). Working in the other transport direction, golgin-97 on the TGN binds to the Rab11 effector FIP1/RCP to regulate incoming traffic from endosomes (Jing *et al.*, 2010). Golgins, in general, bind to multiple families of small GTPases, particularly Rabs, to cytoskeletal proteins including linkers for both actin and microtubule networks and to SNAREs (Goud and Gleeson, 2010; Munro, 2011). This has led to one view of golgins forming a net around the TGN for capturing trafficking machinery (Munro, 2011), and certainly of being key players in post-Golgi transport.

Modifying lipids for tubulation

A variety of lipid modifying enzymes and lipid transfer proteins have been implicated in tubule formation and fission at the TGN, together with protein assemblies. FAPP2 is an adaptor that interacts preferentially with PI4P via its PH domain and with ARF1 on tubular domains of the TGN, it is found only at the tubule junction and not after fission of VSV-G-containing carriers (Godi *et al.*, 2004). Lipid transfer proteins such as CERT and OSBP1 are similarly recruited, potentially regulating the nature of the lipid microenvironment for tubulation

(De Matteis and Luini, 2008). Phospholipase A2 (PLA2) causes tubulation of the TGN membranes by regulation acetylation of phospholipids (Ha *et al.*, 2012). Various PI3Ks, including PI3K δ , VPS-34, and PI3KC2 α , have been implicated in budding of constitutive carriers, CCV and neurosecretory granules from the TGN, anticipating the additional involvement of 3-phosphoisositides at the TGN for membrane fission (Domin *et al.*, 2000; Jones and Howell, 1997; Low *et al.*, 2010).

Membrane fission

Protein kinase D (PKD) has become well-known as a membrane fission agent at the TGN to generate vesicular or pleomorphic carriers, following the implication of this kinase as the target of a marine inhibitor ilimaquinone which vesiculates the entire Golgi (Takizawa *et al.*, 1993). The trimeric G proteins, G $\beta\gamma$ induces PLC-driven diacylglycerol (DAG) production at the TGN and this in turn recruits PKD to activate the protein kinase, PKC η , which phosphorylates and activates PKD (reviewed in Campelo and Malhotra, 2012).

PKD also binds to ARF1 and interacts with a key set of GTPase effectors, the Bin/amphiphysin/Rvs (BAR)-domain containing family of ARFaptins to regulate fission (Gehart *et al.*, 2012). The banana-shaped BAR-domains of several families of BAR-domain containing proteins on the TGN, sense membrane curvature and regulate fission (McMahon and Gallop, 2005). BAR-domain-containing proteins work together with the GTPase dynamin for membrane fission (Meinecke *et al.*, 2013). The ubiquitous dynamin2 isoform performs fission of carriers at the TGN, for a selective subset of apical carriers in polarized transport (Jones *et al.*, 1998; Kreitzer *et al.*, 2000). Other fission proteins like CtBP3/BARS, drive fission in dynamin-independent pathways (Bonazzi *et al.*, 2005). Following fission, loaded carriers are at the behest of microtubules and motors such as KIFs for their transport and delivery.

Actin, myosins, and tubules

Short actin filaments surround the Golgi complex (Percival *et al.*, 2004) and actin, paired with various myosin motors, is intimately involved in the deformation of membranes, carrier fission, and movement. GOLPH3 bridges the PI4P-rich TGN membrane and actin filaments via the motor Myo18a to exert tensile forces for pulling membranes into buds and tubules (Dippold *et al.*, 2009). MyosinIIA is found associated with several types of post-Golgi carriers emerging from the TGN. MyosinII is an effector of Rab6 in which guise it regulates post-Golgi transport and maintenance of Golgi cisternae and stack morphology (Miserey-Lenkei *et al.*, 2010; Storrie *et al.*, 2012). MyosinII is found on subpopulations of tubules during budding at the TGN and on some carriers as they move into the cell periphery (Ikonen *et al.*, 1997; Wakana *et al.*, 2012). Myosin1b working with actin foci, is also implicated in the formation of tubules for post-Golgi transport; disrupting myosin1b induces shape changes in tubules and the TGN (Almeida *et al.*, 2011). These and many other examples give testament to the close links between actin, myosins, and membranes at the TGN.

Rabs and SNAREs

Of the 60 or more mammalian Rab family members, about one-quarter of them are associated with the Golgi or its

emergent transport pathways. These include Rabs 6, 33B, 1, 2, 43, 18, 32, 13, 27, 30, 37, 26, 22, and 3 and relevant yeast family members, Ypt1, 6 and 32 (Goud and Gleeson, 2010; Liu and Storie, 2012). The Rab6 splice variants Ra6A and 6A' are the best known of the TGN-associated Rabs. In addition to roles exerted through myosinII (above), Rab6 has roles in trafficking cargo out of the TGN, for instance in complex with Rab8 and the scaffold MICAL3 (Grigoriev *et al.*, 2007; Grigoriev *et al.*, 2011). Rab 6A and 6A' also regulate TNF trafficking out of the TGN in macrophages (Micaroni *et al.*, 2013). Many of the other Rabs associated with the TGN are implicated through roles on exiting or incoming carriers.

Various SNAREs and fusogenic complexes have been found on the Golgi complex, the best known of which are involved in transport between the ER and early Golgi in mammalian cells and yeast (Malsam and Sollner, 2011). SNAREs must be loaded into carriers for transport to the fusion site. During budding the SNAREs can assemble with cargo, Rabs and Rab-GEFs via tethering proteins, such as GARP at the TGN (Perez-Victoria and Bonifacio, 2009). Two SNARE complexes identified as residents on the TGN for fusion of incoming transport from different endosomes are syntaxin16/Vti1a/syntaxin 6/VAMP4 together with Rab6 and the complex syntaxin16/Vti1a/syntaxin10/VAMP3 (Ganley, 2008; Mallard *et al.*, 2002).

Concluding Remarks

The number of molecules required for sorting and transport at the TGN grows ever larger, unsurprisingly, given the vast and complex postal service run from this organelle. Common principles governing the sorting and transport of proteins and lipids continue to emerge from studies in model organisms and human cells and from insights gained from human disease. Future studies will benefit from the power of genomics and bioinformatics to reveal complete gene networks and from new innovations in microscopy and imaging to visualize these fascinating cell processes.

Constitutive and Regulated Secretion

The eukaryotic cell relies heavily on spatiotemporal organization for optimal function. Constitutive secretory transport is a fundamental cellular positioning system by which a large fraction of the eukaryotic proteome (roughly 30% in mammals) is biochemically processed and transported from the site of synthesis, the endoplasmic reticulum (ER) to various appropriate final cellular destinations in its chemically mature form. Membrane transport is thus responsible for controlling the size, shape, and molecular composition of most cellular organelles, including the plasma membrane, and for mediating the secretion of thousands of cargo species, including hormones, growth factors, antibodies, matrix and serum proteins, digestive enzymes, and many more. Other eukaryotic positioning systems that operate in the cytoplasm (Lee *et al.*, 2013) and in the nucleus (Cavalli and Misteli, 2013) exist in the eukaryotic cell; however, they are much less well understood than membrane transport so far.

The regulation of secretory transport is a central issue in cell biology. Historically, there has been a long-standing distinction in the field of membrane transport between constitutive and regulated secretion (Burgess and Kelly, 1987). For several years, it has been held that, while constitutive transport is a general housekeeping process (see below), regulated secretion is restricted to a limited number of cell types and to the last stages of secretion, namely the fusion of a transport carrier with the plasma membrane (Burgess and Kelly, 1987). Cells such as, for instance, chromaffin or pituitary cells can generate granules containing large amounts of secretory material from the last station of the Golgi complex, the *trans*-Golgi network (TGN) (Burgess and Kelly, 1987; Tooze, 1991). These granules remain quiescent in the cytoplasm until cells are challenged by extracellular signals through plasma membrane (PM) receptors, resulting in signaling cascades that rapidly trigger the fusion of the granules with the PM and the release of their content outside the cell. Other cells do not possess secretory granules and secrete their cargo in an apparently continuous fashion. It was therefore thought that constitutive transport is not regulated, and this has been indeed the prevailing view for a long time. In the last decade, however, it has become clear that constitutive secretion also is potentially regulated by different kinases and signaling pathways at multiple stages of the transport pathway, with important physiological consequences (Simpson *et al.*, 2012; Cancino *et al.*, 2014; Chia *et al.*, 2012; Farhan *et al.*, 2010; Pulvirenti *et al.*, 2008; Mitrovic *et al.*, 2013). The regulation of constitutive transport is the central theme of this section.

The Regulation of Constitutive Secretion

Constitutive secretion begins with the translocation of soluble secretory cargo or membrane proteins into the lumen or the

membrane of the ER, respectively. Transport then continues with the transfer of cargo to the Golgi complex via the intermediate compartment and through the *cis*-, *medial*- and *trans*-Golgi sub-compartments to the TGN, the last Golgi station. At the TGN, cargo proteins are sorted into specialized membranous carriers for delivery to their appropriate cellular destinations, such as the apical or basolateral PM or the endolysosomal system, where cargo continues to be transported until it reaches a state of dynamic equilibrium at a suitable location. Each of these transport stages is balanced by suitable retrograde compensatory fluxes of membrane and proteins in order to keep the morphological and compositional homeostasis of the system. Finally, proteins that need to be degraded are delivered to two degradative systems by which cells regulate the concentration of misfolded and unwanted proteins, one located in the ER (endoplasmic reticulum-associated degradation (ERAD)), and another in the lysosome. This very large and complex apparatus is continuously challenged by exogenous signals or perturbations and by changing internal cellular states.

There are three general reasons for which the transport apparatus requires a sophisticated regulatory system to supervise its activities. One is to respond to environmental signals and demands; another is to support the homeostasis and the robustness of the transport apparatus itself (where robustness is the ability to function optimally under variable and uncertain conditions); and a third is to coordinate the activity of the transport apparatus with those of other cellular modules, such as energy production or motility. Indeed, there is increasing evidence that a large number of signaling molecules reside in the secretory organelles to control transport itself as well as other cell functions (Sallese *et al.*, 2006; Farhan and Rabouille, 2011; Cancino and Luini, 2013; Mayinger, 2011; Figure 1). The mechanisms and principles of this regulation are just beginning to be understood.

Extent of the Regulation Network of the Secretory Pathway

There are two main lines of evidence based on screening and on focused approaches that indicate that the cellular potential for regulation of the secretory machinery is very large.

A number of recent screening studies based on systematic depletion of the kinases and phosphatases as well as other human genes, have sought to unravel the signaling components that control cargo processing and transport as well as the morphology of the secretory pathway (Pelkmans *et al.*, 2005; Bard *et al.*, 2006; Chia *et al.*, 2012; Farhan *et al.*, 2010; Simpson *et al.*, 2012; Mitrovic *et al.*, 2013). What emerges from these investigations is that hundreds of kinases and phosphatases are involved in the regulation of the transport

Figure 1 Golgi-based signaling molecules that regulate Golgi transport. Kinases, phosphatases, phospholipases, phosphoinositides, and second messengers that are involved in Golgi signaling and in controlling the traffic machinery. Reproduced with permission from Cancino, J., Luini, A., 2013. Signaling circuits on the Golgi complex. *Traffic* 14 (2), 121–134. doi: 10.1111/tra.12022. Epub 2012 Nov 15. Review. PMID: 23078632.

machinery affecting protein traffic as well as organelles morphology and organization. A large fraction of the signaling molecules controls cargo transport at the level of the ER and affects Golgi transport. Several kinases and phosphatases also affect the Golgi morphology (Chia *et al.*, 2012; Farhan *et al.*, 2010) as well as the glycosylation of cargo proteins that occurs in the Golgi, with potentially major functional consequences (Chia *et al.*, 2012). These dramatic effects are associated with the presence of many different phospho-proteins on the Golgi membranes (Farhan and Rabouille, 2011; Farhan *et al.*, 2010; Zacharogianni *et al.*, 2011).

In addition, a number of focused studies have shown that the flux of protein trafficking at specific stages of the secretory pathway is under the control of kinases (De Matteis *et al.*, 1993; Cancino and Luini, 2013; Farhan and Rabouille, 2011; Mayinger, 2011). There are well-characterized examples to support this case. One is the effect of protein kinase D (PKD) (Bossard *et al.*, 2007; Malhotra and Campelo, 2011) on transport out of the Golgi. Others, among many, are the effects of the tyrosine kinase Src (Pulvirenti *et al.*, 2008) on different phases of intra-Golgi transport, or of the mitogen activated protein kinases (MAPK) (Farhan *et al.*, 2010; Zacharogianni *et al.*, 2011) and of protein kinase A (PKA) (Cancino *et al.*, 2014; Cabrera *et al.*, 2003) on transport at the interface between the ER and the Golgi. PKA also regulates the constitutive TGN-PM transport (Muniz *et al.*, 1996, 1997). Several reviews of these and other similar studies are available (Cancino *et al.*, 2013; Cancino and Luini, 2013; Farhan and Rabouille, 2011; Mayinger, 2011).

This type of data, however, remains fragmentary at this stage. While these observations do indicate that, as noted, constitutive traffic can be extensively regulated, they do not provide a clear comprehension of the physiological significance of this regulation, as such comprehension would require that the information flow through these regulatory pathways be identified, with a definition of the specific activatory inputs, signaling cascades and effector molecules inducing specific cellular responses. This type of information has been so far partial and limited to a small number of cases, some of which are discussed below.

Traffic Regulation in Response to Environmental Signals and Demands

In a few cell types that have been studied, it has been shown that the secretory pathway is controlled by membrane receptors and related signaling pathways. This is presumably a part of physiological cellular responses to external inputs, although the significance of such responses is not always clear.

The first reported example of regulation of constitutive secretion by a PM sensor was concerned with the activation of the IgE receptor in mastocytes. The activation of the protein kinase C (PKC), which regulates the assembly of the COP-I vesicle involved in the intra-Golgi transport is required for this response (De Matteis *et al.*, 1993). The IgE receptor accelerates the secretion of glycans in tumoral mastocytic line and modulates the interaction of different vesicle components with Golgi membranes *in vitro* (Buccione *et al.*, 1996).

In other cell types, external and internal stimuli such as nutrients and mitogens are sensed by receptors impinging on the MAPK pathway, and result in the regulation of the number of endoplasmic reticulum exit site (ERES) as well as of the rate of cargo flux leaving the ER (Farhan *et al.*, 2010; Zacharogianni *et al.*, 2011). In particular, the activation of the EGFR activates ERK2 through the MAPK signaling cascade. ERK2 then modulates the formation of ERESs via phosphorylation of Sec16, an important player in the biogenesis of the ERESs and COPII (Farhan *et al.*, 2010). In this case, the activation of the secretory pathway is probably part of a general trophic cellular response to nutrients and growth signals.

Signaling Pathways that Support Homeostasis and Coordination of the Secretory Apparatus with Other Cellular Modules

The transport regulatory systems can also respond to internal cellular states, rather than to external inputs. Transport involves membrane fluxes across the transport compartments and is exposed to internal and external perturbations (Mironov *et al.*, 2001; Pulvirenti *et al.*, 2008; Trucco *et al.*, 2004). Such perturbations have the potential to disrupt the transport apparatus, particularly if they occur at the interface between the ER and the Golgi complex. The ER is up to 10-fold larger than the Golgi (Griffiths *et al.*, 1984), and changes in its membrane output can profoundly alter Golgi morphology and composition if not compensated for by corresponding adaptive changes in the retrograde or anterograde traffic out of the Golgi (Griffiths *et al.*, 1984; Klumperman, 2000; Martinez-Menarguez *et al.*, 1999; Thor *et al.*, 2009; Wieland *et al.*, 1987; Pulvirenti *et al.*, 2008). The compensatory mechanisms can be of two kinds. One relies on the self-assembly properties (Gong *et al.*, 2008; Heinrich and Rapoport, 2005) of the secretory machinery itself. Elegant models have been proposed to explain the behavior of segments of the secretory pathway based simply on the properties and the stoichiometry of the transport machinery molecules involved in those steps (Gong *et al.*, 2008; Heinrich and Rapoport, 2005; Sengupta and Linstedt, 2011). And a second major type of compensatory mechanisms consists of devices that sense the changes/ perturbations in the transport rates and respond quickly and precisely to restore homeostasis, though the activation of signaling and actuating systems (Cancino *et al.*, 2013, 2014).

Thus, at the ER–Golgi interface, membrane fluxes leaving the ER for the Golgi result in the activation of a traffic sensor, or receptor, called KDEL receptor (KDEL-R) at the *cis*-Golgi (Cancino *et al.*, 2014; Giannotta *et al.*, 2012; Pulvirenti *et al.*, 2008). The KDEL-R is a seven-transmembrane domain protein belonging to the PQ-loop protein family (Saudek, 2012) that is distantly related to the G-protein-coupled receptor (GPCR) superfamily (Yee *et al.*, 2013; Zhai *et al.*, 2001) and resembles the GPCRs in topology and fold of the transmembrane helices (Yee *et al.*, 2013; Zhai *et al.*, 2001). The activation of the KDEL-R by transport is most likely mediated by a family of ER resident proteins (Cancino *et al.*, 2014; Giannotta *et al.*, 2012; Pulvirenti *et al.*, 2008), the chaperones, which carry a KDEL signal at their C-terminus and cycle between the ER and the Golgi. Of note, the KDEL-R has been discovered and

characterized as molecules involved in salvaging chaperones leaked out of the ER (Lewis and Pelham, 1990; Munro and Pelham, 1987; Pelham, 1988). We now know that when export from the ER brings chaperones to the Golgi, these proteins bind the KDEL-R (Semenza *et al.*, 1990), which then activates a Golgi pool of the G proteins Gq (stimulatory heterotrimeric G-protein) and Gs (stimulatory heterotrimeric G-protein) and the relative transduction pathways. Gs then activates a signaling cascade at the *cis*-Golgi resulting in the phosphorylation of a large number of Golgi and cytosolic proteins and in the consequent activation of retrograde membrane transport (Cancino *et al.*, 2014). Gq, instead, appears to act by inducing a local release of calcium (Micaroni, 2010) (possibly via stimulation of a PLC and IP3 production) and the activation of the kinase SRC. SRC phosphorylates a large number of proteins, which activate anterograde traffic. Thus, a device based on the KDEL-R and two signaling pathways appears to sense incoming traffic into the Golgi and to activate anterograde and retrograde (Figure 2) traffic steps. This reaction counteracts the accumulation of membrane/proteins that would result from a non-compensated continuous arrival of traffic to the Golgi (Klumperman, 2000; Martinez-Menarguez *et al.*, 1999; Wieland *et al.*, 1987) and helps to maintain Golgi homeostasis.

In addition to regulating the Golgi acutely, the KDEL-R exerts a long-term control on the availability of the transport machinery components. Thus, the KDEL-R regulates the expression of a large number of genes, many of which code for transport-related proteins that localize both in biosynthetic and in endo-lysosomal organelles such as SNAREs, adapter complexes, GTPases, chaperones, Golgi and lysosomal enzymes (Cancino *et al.*, 2014). Most likely, a prolonged activation of the KDEL-R is decoded by the cell as a signal of chronic transport overload, which needs to be compensated by the expansion of the transport pathways.

Also of note, the KDEL-R up-regulate other genes that belong to functional modules that are different from transport, such as mitochondrial and energy metabolism, peroxisomal and lipid metabolism, protein degradation and autophagy (Cancino *et al.*, 2014). These responses indicate the presence of mechanisms that coordinate membrane transport with other cellular functions.

These KDEL-R-centered mechanisms are probably just an example of the regulatory devices that operate at different levels of the transport pathways.

The Conceptual Framework

A useful paradigm to understand the above regulatory processes is the theory of control of complex machines. Cells are composed of modules, or subsystems, that execute functions such as protein synthesis or folding, metabolism, membrane transport, autophagy, and apoptosis (Hartwell *et al.*, 1999; Sontag, 2004; Stelling *et al.*, 2004; Csete and Doyle, 2002). These functional modules and the related organelles must be able to preserve their homeostasis and to operate in a complex, coordinated, sensitive, and robust fashion (Waldherr *et al.*, 2008).

Robustness, complexity and sensitivity are features that modern engineers have incorporated into manmade machines

Figure 2 A control system balances the membrane fluxes between the ER and the Golgi and helps to maintain the homeostasis of secretory compartments. (a) A control system (green arrow) is activated at the *cis*-Golgi face by anterograde traffic from ER to Golgi and accelerates the retrograde fluxes from Golgi to ER as well as anterograde fluxes through the Golgi. This helps to balance the exchange of membranes at the ER–Golgi interface and maintains the homeostasis of the Golgi complex. (b) Scheme of the molecular mechanism involved in the Golgi control system. Transport fluxes that reach the Golgi activate the KDEL-R, which promotes the activation of the Gq and Gs heterotrimeric GTPases at the *cis*-Golgi face. Gs leads to the activation of AC9 to increase cAMP levels. cAMP then activates PKA, which increases retrograde transport via the phosphorylation of many proteins including components of the actin machinery and of the COPI complex (Cancino *et al.*, 2014). Moreover, the KDEL-R activates Gq, which induces the acceleration of anterograde traffic through the Golgi (Pulvirenti *et al.*, 2008). The prolonged activation of the KDEL-R results in the activation of several transcription factors including the cAMP/PKA-regulated CREB1. This in turn results in the upregulation of a number of transport machinery genes as well as of genes involved in other functions (Cancino *et al.*, 2014). Modified with permission from Cancino, J., Capalbo, A., Di Campli, A., *et al.*, 2014. Control systems of membrane transport at the interface between the endoplasmic reticulum and the Golgi. *Developmental Cell* 30, 280–294. doi: 10.1016/j.devcel.2014.06.018. PMID: 25117681.

(Hartwell *et al.*, 1999; Sontag, 2004; Stelling *et al.*, 2004; Csete and Doyle, 2002). For this, they have developed the theory of control. The control system is a central concept of the control theory. Such systems are mechanisms that regulate some basic process executed by a machine, or a factory, often by maintaining the homeostasis of the process despite internal or external perturbations that otherwise might have disruptive effects (Stelling *et al.*, 2004; Kitano, 2007; Csete and Doyle, 2002). Another important concept is that the activities of different modules must be coordinated. Such coordination is provided by specific devices, which manage the interface between modules, that is, in physical terms, the operation of the molecular pathways that coordinate separate modules.

Within this framework, the KDEL-R-based mechanism that senses the membrane fluxes that reach the Golgi from the ER and tends to compensate such fluxes by inducing retrograde as well as anterograde transport out of the Golgi can be viewed as a part of a control system that maintains the homeostasis of the Golgi complex. Similarly, the property of the KDEL-R to up-regulate the expression of genes belonging to different functional modules such as energy metabolism, peroxisomal and lipid metabolism, etc., when subjected to prolonged stimulation, can be seen as part of a coordination device that harmonizes the activity of membrane transport with that of other cellular functions.

Summary and Conclusions

Constitutive secretion has been described for a long time as a protein transport process for cellular housekeeping with no needs for signals. Relatively recently, however, the secretory pathway has been shown to be tightly regulated by a complex network of signaling machineries, PKA (Cabrera *et al.*, 2003; Cancino *et al.*, 2014; Martin *et al.*, 2000; Muniz *et al.*, 1996), PKD (Bossard *et al.*, 2007; Diaz Anel and Malhotra, 2005; Liljedahl *et al.*, 2001; Malhotra and Campelo, 2011), MAPK (Farhan *et al.*, 2010; Simpson *et al.*, 2012; Zacharogianni *et al.*, 2011), SRC (Giannotta *et al.*, 2012; Pulvirenti *et al.*, 2008). One of the most characterized control systems resides at the level of the Golgi apparatus (Cancino *et al.*, 2014; Giannotta *et al.*, 2012; Pulvirenti *et al.*, 2008). The Golgi control system operates by sensing the traffic input into the Golgi through the binding of the KDEL-R (here acting as a traffic sensor) with chaperones that escaped the ER. The KDEL-R then activates a controller; the Gs–PKA pathway, which ‘calculates’ the response and triggers the actuators of retrograde traffic, including the actin-based molecular machinery mentioned above (Cancino *et al.*, 2014). This compensates for the membrane input from the ER, and helps to maintain a suitable size and composition of the involved organelles. It is very likely that other internal control points exist and interact with exogenous signaling networks for optimal tuning of the cellular transport and distribution processes.

Altogether, the mechanisms that regulate constitutive secretion appear to be designed to sense and respond to both endogenous states and exogenous signals or perturbations in a harmonic and complex fashion while maintaining the homeostasis of the transport system.

Glossary

Action potential An electrical signal that travels down a neuron or other electrically excitable cell.

Endocytosis A process that allows cells to engulf and internalize material from the outside.

Hormone A protein or substance that is released into the blood from one cell and which has an effect on distant cells.

Receptor A protein that binds a 'ligand.' Ligands include proteins such as hormones.

Secretory pathway A series of membrane compartments through which proteins travel on their way to be excreted from the cell inside to the outside.

SNARE A particular class of membrane-embedded proteins that catalyzes fusion of biological membranes. It stands for Soluble NSF Attachment Protein Receptor.

Transport vesicle Small membrane compartment that carries select cargo (proteins or metabolites) from one place in the secretory pathway to another.

Summary

The concept of regulated versus constitutive secretion was first described almost 30 years ago. The constitutive pathway is a system where certain proteins synthesized by the cell transit through an intricate lipid membrane network, which ultimately fuses with the cell surface membrane releasing the constitutive protein cargo outside the cell. In this pathway, protein cargo moves unrestrained to the plasma membrane. The regulated system shares many features in common with the constitutive system except in the regulated system as the cargo moves through the membrane network it is diverted into a special storage compartment. This compartment can be triggered to fuse with the cell surface in response to external signals. Many types of regulated secretory pathways, their varied cargos and types of storage compartments housing them have been identified. Differences among these systems are found in how they are made, what cargo they store, how they look under the microscope, how rapidly they release their content to the external environment and what triggers release of these stores. Here we survey constitutive secretion and the different types of regulated secretion and briefly overview the mechanisms that dictate their formation and function.

Overview

The ability of cells to release factors into their external environment serves as a major route for cell-to-cell communication. This fundamental process known as secretion has been adapted for a number of biological processes, which allow cells to respond to changes in their environment, principally to either modulate the external environment or to alert both distant or nearby cells to this change (Derby and Gleeson, 2007). Hormones, for example, are secreted into the bloodstream and travel through the body until they find their specific receptor found on distant cells. The specific interaction

between a hormone and its receptor initiates intracellular signaling events that evoke a particular response.

Of course cells had to develop different kinds of secretory mechanisms to accommodate different environmental conditions. This called for the development of secretory systems that could release factors only under the right circumstances. In addition, the timescale of secretion needed to be tailored for specific functions – some extremely rapid on a millisecond timescale for purposes such as neurotransmission in the brain (Südhof, 2013), and others far slower that could sustain longer-term responses, such as release of antibodies to combat pathogens (Borghesi and Milcarek, 2006). In the case of the slower more tonic forms of secretion it is feasible for cells to match the secretory demand simply by manufacturing the required amount of protein as needed. However, in the case of rapid secretion, protein synthesis is too slow to keep up with this demand and so different kinds of release mechanisms are needed. To match this biological need, cells evolved the ability to store newly synthesized material until required, in some cases for very long periods of time (Burgess and Kelly, 1987). The former type of secretion is commonly referred to as 'constitutive secretion' and the latter as 'regulated secretion' (Figure 1).

The average cell makes more than 10 000 different kinds of proteins and each protein is endowed with a unique function, and often a unique location within the cell. Proteins enter the secretory pathway upon synthesis on the endoplasmic reticulum (ER), whereupon they are imported into the lumen if they are soluble secreted proteins, or embedded into the ER membrane if they function as integral membrane proteins (Figure 1). The ER has a unique chemical environment, which allows membrane or soluble proteins to fold into their correct 3-dimensional structure (Derby and Gleeson, 2007). Protein folding is a highly complicated process that sometimes goes awry. Because of this the ER utilizes a range of quality control safety checks on newly synthesized proteins to determine if they are correctly folded. If proteins are improperly folded, they are pumped out of the ER and degraded (Vembar and

Figure 1 Exocytosis and endocytosis. Soluble protein cargo and membrane protein cargo is synthesized at the endoplasmic reticulum (ER) and transported through the secretory pathway. At the trans-Golgi network (TGN) cargo is sorted into constitutive or regulatory secretory vesicles that are either targeted for exocytosis and fusion with the cell surface or are sorted into intracellular transport vesicles destined for the endocytic pathway, such as early endosomes (EE), late endosomes (LE), or lysosomes. Membrane protein cargo is endocytosed into EE and either recycled to the cell surface via the recycling endosomes (RE) or moved into the degradative pathway through LE to lysosomes.

Brodsky, 2008). Examples include mutant forms of CFTR, which are depleted by ER-associated degradation leading to cystic fibrosis (Lukacs and Verkman, 2012). If a protein passes the safety check in the ER it is packaged into lipid bilayer-enclosed transport vesicles that are delivered to the next compartment in the secretory pathway, the Golgi apparatus. Here proteins can undergo an array of posttranslational modifications such as the addition of sugar residues. Once proteins have navigated their way through the Golgi to the trans-Golgi network (TGN) they can be ushered to one of several possible routes. Proteins destined for constitutive secretion are packaged into post-TGN vesicle carriers that move and fuse with the cell surface in an unrestrained manner, thus releasing cargo into the extracellular environment. Cargos of the regulated secretion pathway are packaged into different carriers stored inside the cell for days or even weeks until they receive an instruction to fuse with the cell surface (Burgess and Kelly, 1987; Figure 1).

Cargo of the regulated secretory pathway includes components of the endocrine (e.g., peptide hormones such as insulin, glucagon, neuropeptides, and adrenocorticotrophic hormone (ACTH)) and exocrine systems (e.g., digestive enzymes manufactured by the pancreas). While these molecules are all soluble proteins, regulated secretory cargo can also include membrane proteins such as nutrient transporters. Here, however, the regulated secretory process is generally used to insert those membrane proteins into the cell surface

membrane rather than secrete them from the cell. Other regulated secretory cargo includes metabolites, such as the amino acid glutamate, which acts as a neurotransmitter.

A major function of the regulated secretory pathway is to rapidly deliver a packet of cargo to the plasma membrane that can be released in a burst. While examples of regulated secretion can be found amongst single cell eukaryotes, the system is more widely used in multicellular organisms, which rely on the ability to respond in various ways to intra- and inter-cellular stimuli with both speed and functional purpose. As such, the regulated secretory process plays a central role in mediating various forms of cell communication ranging from endocrine signaling to neurotransmission.

How Do We Know about Regulated versus Constitutive Secretion?

The first observations that distinguished regulated secretion from constitutive secretion were made by simultaneously following the release of two different sets of cargo – viral glycoproteins versus ACTH – from cells cultured in the laboratory. ACTH is produced in the cell from a much larger precursor protein called Pro-opiomelanocortin (POMC). POMC is cut or processed into a discrete set of smaller peptides by enzymes known as convertases or peptidases during the maturation of regulated secretory vesicles (Zhou *et al.*, 1999). These smaller peptides are released via the regulated secretory system and each one has a unique receptor on a specific target cell to which it can bind. This enables one single cell, in this case the POMC producing cell, to transmit different kinds of information to multiple cells within the same multicellular environment.

When comparing the secretion of ACTH and the viral glycoprotein, both proteins were found to pass through the Golgi apparatus as determined by their ability to undergo Golgi-specific glycosylation events (Gumbiner and Kelly, 1982). Yet, the secretion of ACTH was greatly stimulated when cells were exposed to chemicals (secretagogues) that mimicked the second messenger of a stimulatory signal transduction pathway. In contrast, the viral glycoprotein was released from cells at a constant rate. In addition, using physical methods to separate intracellular compartments, it could be demonstrated that ACTH accumulated in a membrane-enclosed compartment, which did not contain the viral glycoprotein. This storage compartment represents the key feature of the regulated secretory pathway, housing a variety of constituents for release only when the appropriate stimulus is received.

Tour of Regulated Secretion

To exemplify the form and function of the regulated secretory system, let us consider the consumption of a meal, a process common to all animals that involves a number of regulated secretory systems (Figure 2). Note that a disruption to any one of these functions contributes to many common diseases in humans including anorexia nervosa, diabetes, and obesity.

Synaptic transmission is responsible not only for thinking about food, but also for triggering the motor activity required

Figure 2 Regulated Secretion. A, Glucose-stimulated insulin secretion in beta cells exemplifies hormone protein secretion. Glucose enters the beta cell via a glucose transporter (GLUT) (1) and is metabolized via the mitochondrion (mito) and ATP is produced. This increases the ATP to ADP ratio (2), which activates the potassium (K^+) channel that exports K^+ from the cell (3). This leads to a voltage change ($\Delta\Psi$) that opens the calcium (Ca^{2+}) channel (4), triggering fusion of insulin granules with the cell surface and release of insulin. B, Insulin-stimulated translocation of GLUT4 to the cell surface in fat and muscle cells exemplifies exocytosis of membrane proteins. Insulin-binding to the insulin receptor (IR, 1) activates the PI3K/Akt signal transduction pathway (2) that triggers movement of GLUT4 containing vesicles to the cell surface (3) and fusion with the cell surface (4). This embeds GLUT4 in the cell surface membrane and allows glucose uptake into the cell (5). C, Glutamine release at the synapse in neurons is displayed as an example of metabolite cargo secretion. An action potential (1) results in Ca^{2+} influx (2) that triggers fusion of synaptic vesicles containing the neurotransmitter glutamate (Glu) with the synaptic cell surface (3) and release of glutamate into the synaptic cleft, where glutamate binds to cell surface receptors to trigger a postsynaptic response (4).

for finding it. At the center of neurotransmission is the generation and fusion of synaptic vesicles with the neuronal cell surface membrane (Figure 2(c)). This releases chemical neurotransmitters into the synaptic cleft, the small gap between adjacent cells, to evoke electrical changes in downstream neurons or muscle cells (De Camilli and Jahn, 1990; Südhof, 2004). Most synaptic vesicles contain small chemical neurotransmitters such as glutamate that are pumped into the lumen of the synaptic vesicle by a transport protein. Most cells possess large reservoirs of glutamate since it is obtained in the diet or via protein breakdown and so this kind of secretion mechanism does not require the cell to manufacture the secretory factor. Synaptic vesicles are induced to fuse with the cell surface in response to increased levels of the intracellular second messenger calcium, which enters through channels found in the surface membrane of the cell.

The entry of food into the digestive system triggers numerous secretory events essential for breaking down food into its individual digestible components, such as sugars, fats, and amino acids. This includes the release of enzymes by the exocrine pancreas to aid digestion. These enzymes are released by pancreatic acinar cells, which synthesize and store proteases and lipases, to breakdown large proteins and fat molecules in the lumen of the intestine (Messenger et al., 2014). Individuals lacking proper exocrine function suffer from pancreatic insufficiency, cannot digest food correctly, and develop nutrient malabsorption and malnutrition. Secretion of pancreatic exocrine factors is triggered by several stimuli including parasympathetic neurons, which release acetylcholine (ACh) via their own regulated secretory process. ACh receptors on acinar cells evoke production of a different kind of second messenger called IP3 (inositol-triphosphate). IP3 then binds to a specific IP3 binding protein on the membrane of the ER and triggers

the release of calcium from this organelle. This calcium signal causes enzyme-containing storage compartments (zymogen granules) to fuse with the cell surface and empty their contents into the gut.

Once food is broken down, its minimal components are absorbed across the intestinal wall for entry into the bloodstream. Specific cells in the pancreas sense some of the incoming dietary components, such as glucose (Aguilar-Bryan et al., 1995). These insulin-producing pancreatic beta cells become more energized by higher blood glucose leading to an increase in the ratio of ATP/ADP inside the cell (Figure 2(a)). This inhibits a potassium (K^+) channel that ultimately results in decreased voltage across the plasma membrane of the pancreatic beta cell. This voltage change ($\Delta\Psi$) causes the opening of another channel, a calcium (Ca^{2+}) channel (Henquin, 2000). The resulting elevation in intracellular calcium leads to fusion of insulin-containing granules with the cell surface releasing insulin into the bloodstream (Hou et al., 2009). Defective insulin secretion or insulin action contributes to diabetes in humans (see Box 1).

A major role of insulin is to stimulate glucose uptake into muscle and adipose tissue where it can be stored either as glycogen or triglyceride for subsequent use during times of energy demand. The ability of insulin to regulate glucose uptake in these organs is accomplished by triggering another regulated secretory pathway in these tissues that results in the mobilization of a glucose transporter known as GLUT4 from intracellular stores to the cell surface (Figure 2(b)). In contrast to the dense-core granules that release their cargo such as pancreatic zymogens or insulin outside the cell, GLUT4 storage compartments fuse with the cell surface and the glucose transporter is incorporated into the surface membrane (Bryant et al., 2002; Stöckli et al., 2011). This exposes GLUT4 to

Box 1 Diabetes – a disease of defective regulated secretion

There are two kinds of diabetes – Type 1 and Type 2. Type 1 diabetes, which commonly occurs in younger children, is due to autoimmune destruction of the pancreatic insulin-producing cells (Yoon and Jun, 2005). This involves beta cell autoantigens on antigen presenting cells that in turn activate cytotoxic T cells that then kill the body's own beta cells. Individuals with Type 1 diabetes therefore lack the ability to produce and release insulin after a meal and if untreated results in death due to an inability to store and utilize energy. For this reason, the discovery of insulin represents one of the greatest medical discoveries of modern times. Type 2 diabetes develops from an impaired response to insulin. Normally, insulin causes glucose to be absorbed by muscle and fat cells in the body, in part by using the regulated secretory system to move GLUT4 glucose transporters from intracellular vesicles to the plasma membrane (Bryant *et al.*, 2002; Stöckli *et al.*, 2011). This response becomes defective in certain people who are at risk of developing Type 2 diabetes. This defect, often referred to as insulin resistance, is associated with obesity and lack of physical activity. The body's response to insulin resistance is to secrete even more insulin from the pancreas to compensate for this defect. While this helps in the short-term, over time this additional burden on the pancreas may in certain individuals ultimately compromise the normal function of the pancreatic insulin-producing cells again leading to destruction of these cells and to diabetes (Ogihara and Mirmira, 2010).

glucose on the outside of the cell enabling it to ferry glucose into the cell. This process plays an essential role in removing nutrients, such as glucose, from the bloodstream after a meal. When it has fulfilled its task, GLUT4 moves back into the cell and is repacked into storage vesicles so that it can repeat this process many times. Defective GLUT4 exocytosis is a hallmark of insulin resistance and type 2 diabetes (see **Box 1**).

Most meals are also accompanied by a beverage, which results in production of glomerular filtrate by the kidney filling the bladder with urine. The bladder responds by using a regulated secretory response. Whereas for the above described processes the objective is to secrete proteins or small molecules outside the cell, the bladder uses the secretory pathway to add extra membrane to the cell surface so that the bladder can expand (Apodaca, 2004). This is accomplished by the unique properties of the umbrella cells lining the bladder. These cells possess a large intracellular reservoir of membranes that can be rapidly added to the surface membrane facilitating a doubling of the bladder surface area. This process is activated by stretch and pressure due to increased urine volume. Two other secretory mechanisms guard against the release of too much fluid into the bladder because this could result in dehydration. Vasopressin is a peptide hormone stored in dense-core secretory granules in posterior pituitary cells in the brain. Loss of fluid from the body results in increased blood pressure and increased osmolarity due to the increased salt concentration. Both of these changes trigger calcium entry into these pituitary secretory cells resulting in vasopressin secretion. Vasopressin increases water permeability of the distal tubule and collecting duct cells of the kidney allowing water to be reabsorbed into the blood. This is mediated by the mobilization of aquaporin

water channels from intracellular stores to the cell surface in these kidney cells (Ward *et al.*, 1999). As in the case of GLUT4, aquaporin is a membrane protein stored inside the cell in storage vesicles that fuse with the cell surface making aquaporin part of the surface membrane enabling it to transport water either in or out of the cell.

The Steps of Regulated Exocytosis

As indicated from the above examples, all regulated secretory processes share a set of conserved common principles (Burgess and Kelly, 1987; Derby and Gleeson, 2007):

Making the Regulated Secretory Compartment

The first specialized feature of the regulated exocytic process is the biosynthesis of the secretory compartment inside the cell – typically a discrete vesicle, that can house and store cargo for later release. This means cargo, such as hormone proteins or other cargo, has to be delivered to these compartments while other proteins such as constitutive secretory cargo need to be excluded from those compartments. Because the average cell produces in the order of 10–20 000 different proteins, sorting the secretory cargo from this sea of protein requires considerable regulation. The regulated secretory systems of multicellular organisms have evolved at least three different mechanisms to achieve this specificity and this is based upon the type of secretory cargo. Here we consider soluble protein hormones, membrane proteins and small molecules such as amino acids, as these exemplify these three separate pathways.

Protein hormones

Protein hormones such as insulin or neuropeptides are synthesized in the form of a pro-hormone in the ER and trafficked through the Golgi to the TGN (example in **Figure 2(a)**). In the TGN these pro-hormones are sorted away from the constitutive secretory pathway into regulated secretory vesicles. Two models have been suggested, 'sorting by entry,' where sorting motifs on the pro-hormones interact with sorting receptors to enter the budding secretory vesicle, or 'sorting by retention,' where pro-hormones as well as other cargo bud off the TGN as immature regulated secretory vesicles that after removal of nonregulated cargo become mature regulated secretory vesicles and it is likely that the biogenesis of regulated secretory vesicles involves a combination of both models (Arvan and Castle, 1998; Dikeakos and Reudelhuber, 2007; Gondre-Lewis *et al.*, 2012; Hou *et al.*, 2009). Several sorting motifs have been identified in pro-hormones, including paired basic amino acids that form a cleavage site for pro-hormone convertases or a 3-dimensional motif on the pro-hormone exposed surface that interacts with the 'sorting receptor' carboxypeptidase E (CPE) and can act as a sorting signal or retention signal (Dikeakos and Reudelhuber, 2007; Gondre-Lewis *et al.*, 2012; Hou *et al.*, 2009). CPE and the pro-hormone convertases contain a short α -helix that binds to cholesterol- and sphingolipid-rich lipid rafts in the TGN, thereby sorting them into regulated secretory vesicles (Tooze *et al.*, 2001). Another sorting mechanism involves aggregation and many regulated

secretory cargo proteins have the capability to aggregate at mildly acidic pH in the presence of Ca^{2+} in the TGN (Dannies, 1999). For example, the hormone insulin forms hexameric arrays and this is coordinated by a direct interaction between insulin and zinc. During maturation of the secretory vesicle pro-hormones such as pro-insulin are cleaved and processed by convertases and CPE that are activated due to the acidified milieu inside the vesicle thus generating mature hormones (Zhou *et al.*, 1999). In the case of insulin the processing leads to insolubility and the formation of large insoluble crystals. This ability to condense into very dense aggregates of protein is reflected morphologically by transmission electron microscopy where they appear as ‘dense-core granules’ owing to the concentrated proteins within them that absorb the stains often used in electron microscopy studies. They are also by definition much larger than most other intracellular organelles, typically of 300 nm diameter. This innate potential to form aggregates serves not only to help guide secretory proteins to their correct destination in the cell but it provides the hormone tremendous stability, protecting it from potential degradation processes. Given that secretory granules exist for many days inside the cell, this property is quite essential. Most importantly, this feature also means that the fusion of one single secretory granule with the cell surface membrane gives rise to the release of a large bolus of bioactive hormone.

Small synaptic vesicles

These vesicles are found in considerable abundance in neurons and are approximately 10 times smaller than protein hormone containing regulated secretory compartments (De Camilli and Jahn, 1990; Südhof, 2004) (example in Figure 2(c) and Box 2). To understand their biology a brief tour of neuronal anatomy and function is necessary. Neurons or nerve cells are excitable cells that may be considered as information transfer units. They sense information from one cell and convey it to others using exocytosis of synaptic vesicles. This process occurs specifically at the neuronal synapse, a specialized region where two neurons almost touch one another. Neurons are made up of a cell body like all cells and this is where the nucleus, the ER and Golgi apparatus are found. In addition, neurons possess two other specialized structures-axons and dendrites. The axons are finger like projections and they make the synaptic connections with other neurons. In some cases axons can be very long, the best example being the laryngeal nerve in the giraffe where a single axon runs for several meters from the brain, all the way down the neck around the heart in the chest and back up to the voice box or larynx in the throat. In fact, Richard Dawkins often defers to this poor design feature as a prime example of evolutionary principle. Synaptic vesicles are enriched at the extreme tips of axons where they make synaptic connections. This design feature made it impossible for this cell to use the same mechanism as those of the soluble protein secretory family because it would simply not be feasible to constantly produce protein in the cell body and transport it all the way to these axonal tips in time for rapid secretory demand. So synaptic vesicles rely on the use of very small molecules such as acetylcholine, serotonin, glutamate, or adrenaline that can be readily synthesized or metabolized in axonal tips. Synaptic vesicles possess transport proteins that

pump these small molecules inside the synaptic vesicle where they are stored until the synaptic vesicle is instructed to fuse with the membrane. This design feature means that synaptic vesicles can be rapidly recharged with their secretory cargo almost upon demand. In some cases neurons reabsorb any unused neurotransmitter from the synaptic cleft after a secretory event either directly or via neighboring glia cells so that it can be reemployed for the same purpose. One of the most commonly used class of antidepressant medications known as serotonin reuptake inhibitors block this process thus increasing the concentration of serotonin in the synaptic cleft thus potentiating the signal between the two cells.

Membrane protein exocytosis

Although the terms secretion and exocytosis were first devised to account for the physical release of soluble cargo from the cell to the external environment, this system is also used to selectively place membrane proteins onto the cell surface in certain cells to enable them to rapidly exchange information in a different way (example in Figure 2(b)). As noted above, two examples of this are the deployment of glucose transporters to the cell surface in adipocytes and muscle cells or water channels in bladder or kidney cells (Stöckli *et al.*, 2011; Ward *et al.*, 1999). The intracellular secretory storage vesicles are often small (50–100 nm in diameter) and once the membrane protein cargo has been delivered to the cell surface membrane they are not released from the cell like soluble cargo but rather they can be reabsorbed back into the cell in a process known as endocytosis (see Box 2). In contrast to soluble cargo, which is found entirely inside the secretory organelle, membrane proteins span the membrane and often possess protein domains on both sides of the membrane. The domains that are located on the cytosolic side often possess address tags or targeting signals that are recognized by sorting machinery in the cytosol whose job is to escort these proteins back to their correct destination – the small recycling secretory vesicles.

Storage Inside the Cell

Once made, the regulated secretory compartments, whether dense-core granules, vesicles or other carriers, are stored within the cell. Depending on the cell and the cargo, these compartments can be stored for long periods of time. In addition, many of these mature storage compartments behave as though they are largely isolated from the rest of the secretory and endocytic pathways since little material is exchanged between the storage compartments and other intracellular compartments. At some point, these compartments will fuse with the cell surface, and often these compartments are positioned within the cell to optimize this latter activity. For some dense-core granules, this involves transporting and positioning the granules near the cell surface, and this is achieved by linking the granule to the cytoskeleton. Positioning of synaptic vesicles is also a key aspect for their function since they must fuse quickly with the cell surface upon the stimulus and as noted above they must fuse in the right place (the synapse) within the cell surface membrane so that the neurotransmitter is secreted into the cleft where two neurons are almost touching (Südhof, 2013). This process is often referred to as pre-docking

Box 2 Synaptic transmission – the fastest regulated secretory system

One of the most complex yet instructive examples of regulated secretion takes place at the synapse and controls the release of neurotransmitters (Burgoyne and Morgan, 2003; De Camilli and Jahn, 1990). Here synaptic vesicles filled with neurotransmitter fuse with the pre-synaptic plasma membrane to release their contents so they can diffuse across to nearby neurons that have neurotransmitter receptors on their surface postsynaptic membrane (Figure 2(c)). All of the basic processes and cellular machinery for regulated secretion are in place for synaptic transmission. However, on top of these basic mechanisms are additional features that allow synaptic vesicles to do something both critical and rare across all the different types of regulated secretory pathways – that is to respond incredibly fast. This is done by using a very fast sensor for calcium and by poising the storage compartment (the synaptic vesicle) at a late stage in the overall fusion process such that only a few molecular rearrangements need to be made before the completion of fusion.

Figure 3 shows an overview of the process and revolves around the action of synaptotagmin, a calcium-binding protein that binds calcium with the same fast kinetics that is shown by the overall process of synaptic vesicle fusion. The storage compartment for most neurotransmission is derived continuously from the endocytic pathway as many of the components of discrete intracellular neurotransmitter vesicles are retrieved from the plasma membrane. These components can be directly endocytosed together following what is known as a 'kiss-and-run fusion' event where the synaptic vesicle remains largely intact after fusion. Alternatively, synaptic vesicle components can be more dispersed whereby specialized synaptic vesicles form after trafficking more deeply through the endocytic pathway.

Neurotransmitters are transported into synaptic vesicles through the combined action of an exchanger, which concentrates neurotransmitters such as glycine, dopamine, and glutamate into the vesicle lumen using a proton gradient, and a nearby proton ATPase pump that establishes the proton gradient. Once filled, the synaptic vesicles are immobilized in specialized areas of the membrane where fusion can take place. Here synaptic vesicles undergo 'docking' with the plasma membrane and a 'priming' step making them ready to undergo the last stages of fusion when the appropriate signal, a spike in intracellular calcium, is given (Figure 3). This primed state is thought to involve a state in which SNARE complexes are already partially formed and may also position the lipid bilayers of synaptic vesicles and the cell surface in a state where membranes have an intermediate stage of fusion called hemifusion, a state where the outer but not inner leaflet of the membranes has fused (Chernomordik and Kozlov, 2005). The ability to arrest fusion at this precarious state is afforded by a number of specialized proteins including synaptotagmin and complexin. In the absence of calcium, synaptotagmin binds SNARE complexes and prevents them from catalyzing full fusion. An action potential traveling down the axon will activate voltage-gated calcium channels allowing calcium to enter the cell near the docked synaptic vesicle. Synaptotagmin binds calcium via special calcium binding domains that allow synaptotagmin to bury itself into the surface membrane and also bind stronger to SNARE complexes – now helping to complete the formation of SNARE complexes and complete the fusion process (Rizo and Rosenmund, 2008; Südhof, 2013).

and this enables the fusion process the capability to occur with incredible speed since arguably only one single biochemical step is required to achieve secretion. Exocytic vesicles containing membrane protein cargo also have a very slow rate of exchange with the cell surface under non-stimulated conditions and a specific signal like insulin or vasopressin triggers their fusion with the cell surface (Stöckli *et al.*, 2011; Ward *et al.*, 1999). The fusion of these vesicles is not restricted to a specialized part of the cell surface, unlike synaptic vesicles.

Responding to a Signal

Each different kind of secretory cell responds to a unique signal empowering the system with enormous capacity to respond to a myriad of factors present in the outside world. This might be heat, stretch, pH, nutrients, or the presence of a foreign invader. Cells are designed with the unique ability to respond to these different triggers but usually each individual cell is designed to respond to just one trigger. For example, pancreatic beta cells respond to nutrients but not to heat or stretch. Immune cells respond to foreign material but importantly not to other materials that might be deemed as part of ourselves otherwise this might trigger an undesirable self-attack as in the case of Type 1 diabetes (see Box 1) or other autoimmune diseases such as celiac disease, arthritis, or rheumatic Fever. The sensing of some kind of environmental change triggers a signal transduction pathway inside the cell. As noted above, calcium is a very common intracellular transmitter for many different kinds of regulated secretion but others include cyclic AMP, IP₃, changes in protein phosphorylation, nitric oxide, or specific kinds of lipids. The common elements that make each of these suitable as signal transducers is that each of them can be rapidly and readily acquired because of their abundance or the ability of cells to rapidly manufacture them, they are short lived so that the signal once generated can easily be extinguished. In the case of regulated secretion, the ultimate outcome is to accelerate the steps that enable vesicles to fuse with the surface membrane.

The Secretory Process

Südhof, Schekman, and Rothman won the 2013 Nobel Prize for Physiology or Medicine for their contributions to the discovery of the machinery that catalyzes the movement and fusion of vesicles in eukaryotic cells (Bonifacino, 2014). Central to their work was the discovery of the SNARE proteins, which are embedded in the membrane and catalyze fusion of vesicles with the cell surface (Rizo and Südhof, 2002; Rothman, 1996; Figure 3). The family of SNARE proteins has many members and different members localize to different compartments in the cell and catalyze distinct fusion events. This is an important aspect of SNARE proteins, since it helps explain the specificity of membrane fusion and why a regulated secretory dense-core granule fuses with the cell surface and not, for instance, with the ER or the Golgi. The second important aspect of SNARE proteins is that those on the vesicle and on the cell surface bind to each other, inducing a very energetically favored conformational change that brings membranes close enough to fuse and override the energy barrier that would

Figure 3 Molecular mechanism of synaptic fusion. Often synaptic vesicles are pre-docked or hemifused under unstimulated conditions and this enables very fast release of cargo once the signal is received. During docking, the SNARE complex is formed and complexin and synaptotagmin are bound to the SNARE complex. This can lead to hemifusion, where the inner leaflet of the membrane bilayer is fused but not the outer leaflet. Once Ca^{2+} is channeled into the synapse, Ca^{2+} binds to the calcium-binding domains in synaptotagmin that triggers binding and insertion of those domains into the cell surface membrane, thus generating a membrane curvature that results in fusion of the vesicle with the cell surface membrane and release of the cargo.

ordinarily keep membranes apart. Essentially, a SNARE protein, which is embedded in the membrane on one end, starts to wrap around other SNARE proteins, which are embedded in the opposing membrane. They start interacting on their free end and then continue to zipper toward the membrane anchors in a process that brings the two membranes close enough to force the melding of the lipid bilayers. For many regulated secretory systems, nature has added additional calcium-binding proteins onto this basic template, which allows fusion to be under the control of a surge in calcium. These calcium-sensitive proteins can work by holding SNARE proteins in an intermediate state during the fusion process, which only proceeds when calcium is present. Many additional proteins act prior to the formation of the SNARE complex, and since their activity can also be controlled, they too can contribute to trigger the fusion of regulated secretory vesicles. These additional proteins include the so-called ‘tethering’ factors, which help attach vesicles to the membranes they are targeted to for fusion. These tethering factors can respond to a variety of queues to help instigate the next steps of SNARE complex formation and thus can serve as trigger points that can induce regulated secretory vesicles to fuse to the plasma membrane.

Constitutive Secretion

Regulated secretion enables cells to respond rapidly, in some cases extremely rapidly, to changes in the outside world (Burgess and Kelly, 1987). This is appropriate as with eating, for example, numerous secretory processes need to be evoked with temporal precision and defects in this timing often lead to disease. Individuals with Type 1 diabetes are required to inject insulin prior to meals. If the timing of this is delayed this can result in major perturbations in blood glucose. Another important feature of regulated secretion is that cells can deliver pre-made contents without having to wait for the biosynthetic

process to synthesize and carry content all the way from the ER. There are many other kinds of secretion, however, for which these requirements are unnecessary and increased synthesis from the ER is an appropriate mechanism to increase the release of particular content into the extracellular environment.

The serum/plasma or the noncellular part of blood is comprised of many proteins with some found at extremely high concentrations – in the order of low millimolar levels. In many cases, these proteins serve what could be deemed as ‘house keeping’ functions. Albumin, one of the most abundant of all, maintains the osmotic pressure of blood and escorts other factors such as lipids and hormones from place to place in the body. Globulins assist in immune function and clotting factors are constantly at the ready to seal any breaks in the vascular system. Here it is not necessary to maintain a regulated secretory system but rather a system that constantly manufactures these proteins and then deposits them into the bloodstream in a completely unrestricted manner, hence ‘constitutive secretion.’ Another example of constitutive secretion is the secretion of antibodies from B lymphocytes, so named because they develop in the bone marrow. Each B lymphocyte can produce a specific antibody that might be directed against a particular pathogen. When that antibody is needed, the appropriate B cell is stimulated to produce large amounts of its particular antibody, which coincides with proliferation of the entire constitutive secretory pathway (Borghesi and Milcarek, 2006). Over the course of days, secretion by stimulated B cells will result in high levels (titers) of those antibodies in the bloodstream. While the production of the antibodies is stimulated, the subsequent release or secretion of the antibodies occurs constitutively. When the pathogen has been destroyed, the B cells are no longer stimulated. They ramp down their production of antibody and diminish the size of their secretory pathway. These resulting ‘memory’ B cells lie in wait to respond if the pathogen is detected in the future.

Conclusion

Secretory systems have evolved to become highly specialized to meet the numerous demands of multicellular life. These systems defend us against foreign attack, they underpin our ability to think, to contract our muscles, to smell and to see. They are crucial for eating and processing food into energy and they aid our ability to grow, fight stress, and to regulate every homeostatic system in our body. There are many different diseases and abnormalities that arise from defects in these secretory systems. All of these systems share a common set of rules and once you have mastered the principles of one, it is very easy to understand others. One of the most powerful aspects of these secretory systems for the future is that almost every cell in the human body secretes factors into the bloodstream. Hence, in a sense the blood is a blueprint for what is going on in every cell in the body. Therefore, one of the hopes of the future is that we can tap this resource to obtain hidden information about the health of different organs and use this information productively to treat disease before it has reached a point where it is no longer treatable. So in many ways both the regulated and constitutive secretory systems could hold the secret to our future long-term health in ways we have not even begun to imagine.

Clathrin and Clathrin-Dependent Endocytosis

FM Brodsky, University College London, London, UK

© 2016 Elsevier Inc. All rights reserved.

Introduction

Clathrin is an intracellular protein present in the cytosol of eukaryotic cells. When recruited to the cytosolic surface of the plasma and intracellular membranes, clathrin can self-assemble into a polyhedral lattice. Polymerization of clathrin organizes the adaptor proteins responsible for clathrin recruitment to membrane surfaces, causing adaptor-associated cargo molecules to concentrate within the clathrin-coated membrane, thereby selecting cargo for transport or sorting (Figure 1; Brodsky, 2012). In this capacity, clathrin-coated vesicles (CCVs) play a key role in endocytosis of many cell surface receptors, internalizing both constitutively active and ligand-gated receptors. CCVs also sort proteins in the trans-Golgi network (TGN) that are destined for lysosomes or for storage granules that undergo regulated secretion and clathrin is required for some recycling pathways. Thus clathrin contributes to selective membrane traffic to and from the plasma

membrane (PM), controlling how integral membrane proteins and their ligands are exposed to the different microenvironments enclosed by intracellular membrane-bound organelles. Patches of clathrin-coated membrane on endosomes and at the PM further mediate segregation of integral membrane proteins to create signaling domains (Kim *et al.*, 2013) or to target proteins for recycling (Majeed *et al.*, 2014) or degradation (Raiborg *et al.*, 2002). Finally, in a less-conserved function, clathrin plays a non-membrane traffic role by participation in microtubule cross-linking during mitosis and stabilizing the mitotic spindle.

Biochemistry of Clathrin

Clathrin is formed by trimerization of three clathrin heavy chain (CHC) subunits near their C-terminus. This forms a triskelion or three-legged shape that readily self-assembles into

Figure 1 Clathrin function in cargo selection during receptor-mediated endocytosis. Step 1: Adaptor complexes (AP2) are recruited to the PM by interaction with the phosphoinositide PI(4,5)P, which causes a conformational change exposing the cargo-binding site. Step 2: Adaptors interact with cargo, which causes a conformational change exposing their clathrin-binding site. Step 3: Clathrin triskelia from the cytosol interact with adaptors and associated cargo. Step 4: Adaptors stimulate clathrin polymerization into a lattice, which can deform membranes into buds and generate coated vesicles containing selected adaptor-binding cargo. Step 5: CCVs are fully formed and excised from the membrane by dynamin polymerization at the vesicle neck. Step 6: The activity of Hsc70 ATPase and auxilin disassembles the clathrin lattice. Step 7: The adaptors are liberated from the uncoated vesicle by phosphoinositide phosphatase activity and the uncoated vesicle fuses into endosomes to deliver its contents. This figure is reproduced from Brodsky, F.M., 2012. Diversity of clathrin function: New tricks for an old protein. *Annual Review of Cell and Developmental Biology* 28, 309–336. Table 1 Clathrin subunits – genes and proteins

Clathrin subunit	Gene name	Human chromosome location	Length of human protein (aa)	Apparent molecular mass by SDS-PAGE (kDa)
Clathrin heavy chain 17 (CHC17)	CLTC	17q.23.2	1675	180
Clathrin light chain A (CLCa)	CLTA	9p.13.3	218-No inserts	34
		8p.22 (Pseudogene)	220-Splice variant s2	35
		12p.13.31 (Pseudogene)	236-Splice variant s1	36
			248-Neuronal splice variant	39
Clathrin light chain B (CLCb)	CLTB	5q.35.2	211-No insert 229-Neuronal splice variant	32 36
Clathrin heavy chain 22 (CHC22)	CLTCL1	22q11.21	1640	170

a polyhedral lattice (Heuser *et al.*, 1987). The triskelion is puckered at the vertex (Ferguson *et al.*, 2008), providing an orientation that favors formation of curved lattices and closure of assembled clathrin into a cage structure. Clathrin was discovered in 1975 by Barbara Pearse and named for the 'latticed' cage that it forms (Pearse, 1975). The triskelion shape was first described 6 years later (Ungewickell and Branton, 1981; Kirchhausen and Harrison, 1981; Crowther and Pearse, 1981).

CHCs

A gene duplication that occurred around the time that vertebrates evolved gave rise to two genes encoding CHCs, CLTC and CLTCL1 (formerly CLTD) (Wakeham *et al.*, 2005). These encode two distinct CHCs, CHC17 and CHC22, named for their human chromosome locations (Table 1). CHC17 binds clathrin light chain (CLC) subunits (see below) and performs the conventional membrane traffic functions associated with clathrin. CLTCL1 has become a pseudogene in mice, so mice are missing CHC22 protein. The status of CHC22 protein in other vertebrates is not known, though CLTCL1 genes appear to be intact in some other vertebrate genomes. CHC22 does not associate with CLCs in cells (Liu *et al.*, 2001). Non-vertebrate species have a single CHC (Wakeham *et al.*, 2005) and plants have two (Baisa *et al.*, 2013; Kania *et al.*, 2014), which appear to be CLC-binding.

The structures of the proximal leg domain and the CHC17 terminal domain have been determined to 2–3 Å resolution by X-ray crystallography (Figure 2; ter Haar *et al.*, 1998; Ybe *et al.*, 1999; von Kleist *et al.*, 2011). Contained within the proximal leg domain is a repeated motif of 10–12 short alpha helices, called a clathrin heavy chain repeat (CHCR). The triskelion leg comprises eight CHCRs (numbered 0–7) and the trimerization domain is partially formed by interactions of three CHCR7s (Ybe *et al.*, 2007), which extend into a longer triple helix coil (Fotin *et al.*, 2004b; Figure 2). CHCR motifs appear singly and multiply in other proteins (Ybe *et al.*, 1999) and for the Vps41 coat protein, the CHCR motif has been implicated in self-assembly, similar to its role in clathrin (Asensio *et al.*, 2013).

CHC17 is recruited to membranes through interaction of its N-terminal domain with the tetrameric adaptors AP1, AP2, and AP3 and the monomeric adaptors GGA1, GGA2, GGA3, and several other adaptors. The terminal domain has a seven-bladed beta-propeller structure, with mapped-binding sites for adaptor proteins between the blades (Lemmon and Traub, 2012; Figure 2). In cells, CHC22 interacts with AP1 and GGA2 and does not bind AP2 (Liu *et al.*, 2001). The protein sequences of human CHC17 and CHC22 are 85% identical, with sequence differences spread throughout (Wakeham *et al.*, 2005), and CHC22 is 35 amino acids smaller (Figure 2). No obvious sequences account for the difference in adaptor preference, thus CHC22 may interact with unknown adaptors that bias its membrane localization. The apparent molecular masses by SDS-PAGE are 180 kDa for CHC17 and 170 kDa for CHC22.

CLCs

Concomitant with vertebrate emergence, there was a gene duplication that gave rise to two genes, CLTA and CLTB, encoding CLCa and CLCb proteins in vertebrates (Wakeham *et al.*, 2005; Table 1). In humans, CLCa and CLCb are ~60% identical in protein sequence, and all vertebrate CLCa sequences are more homologous to each other than to the CLCb sequences from the same species. While the ratio of CLCa to CLCb is characteristic for specific tissues (Acton and Brodsky, 1990), their differential function is presently not known. CLCs associate exclusively with CHC17 in cells, though can interact with CHC22 in yeast two-hybrid assays. Yeast and flies have a single CLC (Wakeham *et al.*, 2005), while some plants have more than two types of CLCs (Baisa *et al.*, 2013).

Biochemical properties have been assigned to linear domains of the CLCs, although the biological functions of some of these domains are not yet elucidated. Target phosphorylation sites for casein kinase 2 unique to CLCb are present at the N-terminus (Hill *et al.*, 1988), and shared phosphorylation sites for GRK (Ferreira *et al.*, 2012), implicated in uncoating, are present at the C-terminus. CLCa has a unique sequence

Figure 2 CHCs – structure and comparison. The location of CHC17 sequences and domains with solved structures are shown in the context of the triskelion. The structures shown are from PyMol (triskelion-accession number 3IYV; TxD-accession number 3LVH; TD-accession number 2XZG; proximal leg-accession number 1B89) and are based on Fotin *et al.* (2004b), ter Haar *et al.* (1998), Ybe *et al.* (1999). The numbering of the domain boundaries is based on human CHC17. The numbered sites on the TD structure are binding sites for adaptors, as detailed in Lemmon and Traub (2012). In the upper left is a side view of the triskelion demonstrating its characteristic pucker (PyMol accession number 3IYV). Below is a linear map of the amino acid boundaries of the eight CHCR structural repeats (0–7) relative to the structural domains of CHC17. This is aligned with the predicted domain structure of CHC22. The red marks indicate characteristic amino acid differences that are conserved in each type of CHC, as determined by DIVERGE (adapted from Wakeham *et al.*, 2005). This figure is reproduced from Brodsky, F.M., 2012. Diversity of clathrin function: New tricks for an old protein. *Annual Review of Cell and Developmental Biology* 28, 309–336.

that stimulates uncoating *in vitro* (DeLuca-Flaherty *et al.*, 1990) and both CLCs have a central calcium-binding domain (Näthke *et al.*, 1990), a sequence that binds the leucine-rich repeat kinase 2 (LRRK2) implicated in Parkinson's disease (Schreij *et al.*, 2015) and a C-terminal calmodulin-binding domain (Pley *et al.*, 1995; Figure 3). Additional diversity in vertebrate CLC protein is generated by RNA splicing (Figure 4; Jackson *et al.*, 1987). The CLTA gene has two exons encoding 12 and 18 residues that are retained in neuronal clathrin, but removed by splicing in the majority of non-neuronal tissues. Splicing that occurs during murine heart development generates an intermediate variant of CLCa with an insert of 12 residues and in brain (Giudice *et al.*, 2014), a fourth splice variant with an insert of 18 residues is detected (Kirchhausen *et al.*, 1987). The CLTB gene comprises an exon homologous to the longer spliced exon in CLTA, generating CLCb with an 18 residue insert in neurons and CLCb with no insert in non-

neuronal tissue. Thus there are four forms of CLCa and two of CLCb, with neurons expressing predominantly the longest forms of both. CLCb has only two cysteine residues, which are located near the C-terminus and readily form an internal disulfide bond under oxidizing conditions *in vitro* (not *in vivo*) (Figure 4). The smallest splice variant of CLCa has only one C-terminal cysteine, but the 12-residue insert introduces a second cysteine to the protein, allowing an internal disulfide to form *in vitro*. The formation of internal disulfide bonds cause a mobility shift of the CLC proteins such that molecular mass can be unreliable for distinguishing between some forms of CLCa and CLCb (Parham *et al.*, 1989). However, specific monoclonal antibodies are available that allow these forms to be distinguished (Brodsky *et al.*, 1987).

CLCs have an extended interaction with CHC17 residues from the trimerization domain at the triskelion vertex to the bend in the triskelion knee (Wilbur *et al.*, 2010; Figure 5). This

Figure 3 CLC protein domains. Domain maps of the vertebrate CLCs, CLCa and CLCb scaled to number of amino acids. Common functional domains indicated include the consensus sequence (CON) shared by all vertebrate CLCs, the calcium-binding sequence (Ca⁺⁺), the heavy chain-binding region (HC), the neuronal inserts of 18 (N-18) and 12 (N-12) residues, the LLRK2-binding domain (L), and the calmodulin-binding domain (CBD). Unique to CLCa is a region that can stimulate the uncoated ATPase, *in vitro* (HSC70). The black arrowheads show identified phosphorylation sites, serines 11 and 13 unique to CLCb (Hill *et al.*, 1988) and serine 205 (human CLCb) and its equivalent in CLCa (Ferreira *et al.*, 2012). Note that numbering varies slightly between species.

Figure 4 CLC diversity due to alternate splicing and internal disulfide bond formation. Alternate splicing produces four forms of CLCa and two forms of CLCb. Amino acid inserts of 18 and 12 residues can be encoded by two exons in *CLTA* and a homologous (but not identical) insert of 18 residues can be encoded by a separate exon in *CLTB*. The 12-residue insert includes a cysteine residue at positions 187 in nCLCa and 169 in s2CLCa, allowing an internal disulfide bond spanning 31 residues that can form with a conserved cysteine at positions 218 and 200 respectively, under oxidizing conditions after purification and during electrophoresis. CLCb and nCLCb have the conserved cysteine at positions 191 and 209 respectively that can form an internal disulfide bond spanning 10 residues with a CLCb-specific cysteine at positions 181 or 199.

stabilizes the trimerization domain (Ybe *et al.*, 2007) and buttresses the whole C-terminal third of the CHC, affecting triskelion flexibility and pucker (Dannhauser *et al.*, 2015). The presence of CLCs increases the tensile strength of the clathrin lattice, which could be influenced by all three of these properties (Dannhauser *et al.*, 2015). Interestingly, the spliced inserts are localized near the CLC C-terminal interaction with the trimerization domain, where they may affect these physical properties of clathrin. CLCs bind members of the Huntingtin-interaction protein (Hip) family (HIP1 and HIP1R in vertebrates, Sla2p in yeast) (Gottfried *et al.*, 2010), via 20 conserved residues near the CLC N-terminus (Chen and

Brodsky, 2005; Legendre-Guillemin *et al.*, 2005; Figure 3). Hips recruit actin and affect actin dynamics, thereby linking the CHC17 clathrin lattice to the actin cytoskeleton. Thus structurally and functionally, CLCs contribute strength to the clathrin lattice.

Clathrin Assembly and Disassembly

Assembly of CHC17 into a polyhedral lattice has been characterized biochemically, and visualized at 8–12 Å resolution by cryo-electron microscopy (Figure 1; Fotin *et al.*, 2004b).

Figure 5 Low resolution structure (7.9 Å) of CLCb bound to CHC17 showing CLCb conformational changes and their effects on assembly. (a) Structure of CLCb bound to the triskelion hub (residues 1074–1675) (Wilbur *et al.*, 2010). The CLCb density is shown as α -helices (yellow). The established structure of CHC17 (Ybe *et al.*, 1999), as fitted to crystallographic density is shown. The brown CHC proximal legs have extended (straight) knees and CLCb density is associated with these knees (arrows). The blue CHC proximal leg has a bent knee, permitted by CLCb bound in the second, retracted conformation (arrowheads). (b) Models of triskelia with all straight or all bent knees are shown. Projection onto clathrin lattices at the right shows that the knee must bend to allow for assembly, facilitated by a conformational change in the CLCb. Both panels are reproduced with permission from Wilbur, J., Hwang, P.K., Ybe, J.A., *et al.*, 2010. Conformation switching of clathrin light chain regulates clathrin lattice assembly. *Developmental Cell* 18, 841–848.

CHC17 can form a lattice in the absence of the CLCb subunits, with key assembly interactions occurring between the proximal and distal leg domains (Wakeham *et al.*, 2003; Bocking *et al.*, 2014). CLCb interaction with the triskelion knee is sensitive to pH changes and can regulate bending, providing a

'brake' on spontaneous self-assembly of CHC17 into a lattice, by extending the triskelion knee (Wilbur *et al.*, 2010; Figure 5). In cells, assembly is promoted by CHC17 interaction with adaptors localized on membranes and is energetically favorable.

During CHC17 disassembly, a disordered C-terminal segment is recognized by the Hsc70 ATPase (Rapoport *et al.*, 2008) and its J-domain-containing cofactor auxilin (Unge-wickell *et al.*, 1995). ATP hydrolysis by Hsc70 is required for clathrin disassembly under biological conditions (Merrifield and Kaksonen, 2014). In spite of available cryo-electron microscopy structures of auxilin fragments and/or Hsc70 bound to CHC17 lattices (Fotin *et al.*, 2004a; Young *et al.*, 2013) and analysis of uncoating kinetics (Rothnie *et al.*, 2011; Bocking *et al.*, 2014), there is still debate about the exact mechanism by which disassembly is triggered by the Hsc70–auxilin complex. Concomitant with clathrin lattice disassembly, disruption of adaptor interaction with their recruiting phospholipids by lipid phosphatases (e.g., synaptojanin, endophilin, and OCRL) contributes to vesicle uncoating (Posor *et al.*, 2014).

It is notable that purified protein or recombinant fragments of CHC17 will self-assemble into a lattice (Greene *et al.*, 2000). Early biochemical studies of purified clathrin assembly described a variety of ionic and nonionic conditions that influence *in vitro* assembly of clathrin (Keen *et al.*, 1979; Nandi and Edelhofer, 1984), an interest that has reemerged with consideration of clathrin's potential as a biological nanomaterial (Hom *et al.*, 2012). CHC22 has a triskelion shape, similar to CHC17 and assembles into larger structures, yet to be characterized. CHC22 is missing the peptide sequence recognized by Hsc70, so will have a different disassembly mechanism.

Cellular Function and Regulation of Clathrin

Clathrin plays a sorting and transport function in membrane traffic for all eukaryotic cells. Its roles in vertebrate, and particularly mammalian cells, are more clearly defined than for yeast and plants. Here the mammalian roles, which correspond to similar pathways observed in *Drosophila* and nematodes, are described first. Then the known clathrin-mediated membrane traffic pathways in yeast and plants will be addressed, followed by discussion of clathrin function independent of membrane traffic.

PM Roles

Receptor-mediated endocytosis

The classic function ascribed to clathrin is to facilitate internalization of ligands bound to integral membrane receptors by receptor-mediated endocytosis (RME) (Figure 1). This function was postulated by Roth and Porter (1964) from observation of clathrin-coated pits (depressions) and vesicles during the uptake of yolk protein in mosquito oocytes (Roth and Porter, 1964). Clathrin's role in RME has since been functionally verified by many approaches. This role is restricted to CHC17. CHC22 clathrin does not naturally interact with the AP2 adaptor, when CHC17 is present (Liu *et al.*, 2001;

Esk *et al.*, 2010). The process of clathrin lattice formation at the PM involves cooperative interactions between receptors and the AP2 adaptor to nucleate clathrin assembly (Cocucci *et al.*, 2012). AP2 is recruited to the PM by specific recognition of phosphatidylinositol (4,5)-bisphosphate (PIP2). PIP2 binding to AP2 causes a conformational change that enhances cargo interaction, as does AP2 phosphorylation (Canagarajah *et al.*, 2013). Receptor (cargo) interaction with AP2 adaptors then induces a conformational change that reveals their clathrin-binding sites (Kelly *et al.*, 2014). Purified CHC17 bound by CLCs does not self-assemble at physiological pH (Ungewickell and Ungewickell, 1991; Liu *et al.*, 1995). Adaptor interaction with CHC17 overcomes this inhibition, presumably by alignment of triskelion legs such that the CLCs are dislodged from their inhibitory position at the knee (Greene *et al.*, 2000). Exposure of clathrin-binding sites upon receptor engagement by adaptors thereby directs clathrin assembly at sites where cargo is present, and presence of the CLCs prevents assembly of empty clathrin cages in the cytosol. For some signaling receptors, ligand binding enhances adaptor binding through receptor phosphorylation, such that RME is inefficient in the absence of ligand binding. Other receptors constitutively interact with AP2 adaptors. Early studies showed that adaptors in the cytosol that are not clathrin-associated are phosphorylated (Wilde and Brodsky, 1996), suggesting an additional regulatory mechanism for preventing nonproductive clathrin-adaptor interactions in the cytosol.

The minimal interaction of receptor domains with AP2 and clathrin at the surface of a PIP2-containing liposome is sufficient for the formation of a clathrin-coated membrane bud (Kelly *et al.*, 2014). In cells, other clathrin-associated proteins may contribute to membrane curvature, such as BAR-domain containing proteins, which are naturally curved and associate with invaginating membranes (Merrifield and Kaksonen, 2014; McMahon and Boucrot, 2011). Successful detachment of a CCV from the PM depends on self-assembly of dynamin GTPases into a protein 'collar' at the site of bud extrusion (Schmid and Frolov, 2011; Ferguson and De Camilli, 2012). Dynamins also contribute regulatory functions at earlier stages of CCV formation (Schmid and Frolov, 2011).

RME of transferrin receptor, low-density lipoprotein receptor and epidermal growth factor receptor can proceed in the absence of CLCs (Huang *et al.*, 2004; Poupon *et al.*, 2008). However, RME of certain G-protein-coupled receptors (GPCRs) requires CLCs (Ferreira *et al.*, 2012). Given that CLCs contribute to lattice rigidity (Dannhauser *et al.*, 2015), they may be required for RME of cargo whose properties increase resistance to membrane bending (Stachowiak *et al.*, 2013). Analogously, the Sec13 subunit of the COPII coat, which enhances coat rigidity, is required for GPI-linked cargo, but dispensable for other vesicle cargo (Copic *et al.*, 2012).

Alternatively, CLCs could be required for RME of selected cargo because some cargo alter membrane properties such that CLC recruitment of actin is needed for effective budding (Brodsky, 2012). RME of selected cargo in some mammalian tissue culture cells can occur in the absence of actin. However, morphological analysis shows that actin is present at the necks of the majority of coated pits in cultured mouse melanoma cells (Collins *et al.*, 2011). RME at the apical surface of polarized cells requires CLCs but RME of the same cargo at the

baso-lateral surface does not (Boulant *et al.*, 2011). In the case of apical endocytosis, the interaction of CLCs with Hip family proteins is required, implicating the CLC–Hip–actin connection in this process. Additionally, the CLC requirement can be reproduced by experimentally increasing membrane surface tension (Boulant *et al.*, 2011). Thus, the absolute requirement for actin recruitment by CLCs during mammalian RME is variable, depending on the force needed for vesicle detachment from the PM. However, it may be that actin participates in budding of most CCVs, whether it is needed or not (Collins *et al.*, 2011).

Particle uptake and domain organization

The size of CCVs can range from 60 to 200 nm in diameter (Pearse and Crowther, 1987). At the neuronal synapse, where clathrin is involved in recapture of synaptic vesicle proteins, CCV size is restricted to the smaller dimensions in this range by the neuronal assembly protein AP180 (Morris *et al.*, 1993). In several instances, clathrin is involved in the uptake of particles and microbes that are larger than 200 nm. In these cases, clathrin assembles at the interface between the microbe and actin. For uptake of *Listeria* bacteria, the CLC–Hip interaction, as well as CHC17 phosphorylation is required at internalization site (Bonazzi *et al.*, 2011). In the extreme instance of enteropathic *Escherichia coli*–host cell contact, clathrin is recruited at the bacterial contact interface to nucleate actin polymerization and pedestal formation. This latter process involves CHC17 phosphorylation and CLC–Hip interaction but no internalization, utilizing polymerized clathrin as a template for actin recruitment (Bonazzi *et al.*, 2011). A similar process accompanies formation of adherens junctions between mammalian cells (Bonazzi *et al.*, 2012). Clathrin-AP2 assemblies are also involved in stabilizing signaling domains (signalosomes) for the developmentally important Wnt complex (Kim *et al.*, 2013), in which the clathrin lattice appears to play an organizational role, as opposed to cargo capture for vesicle formation.

Endosome Roles

Two functions for clathrin on endosomes have been established. Cargo can recycle from sorting endosomes to the PM by many pathways. One of these pathways is clathrin-mediated and involves structures called G (gyrating)-clathrin, which are observed as highly motile clathrin-coated structures in the cell periphery (Zhao and Keen, 2008). G-clathrin mediates rapid recycling of internalized transferrin receptor and is not detected in the absence of CLCs (Majeed *et al.*, 2014). CLCs are also needed for recycling internalized β 1-integrin to the PM and for cell migration, implicating G-clathrin in directed recycling of cargo from endosomes to the leading edge of the PM. G-clathrin utilizes the GGA1 clathrin adaptor. The small GTPases ARF1 and ARF6 are involved in G-clathrin recruitment (Luo *et al.*, 2013).

Patches of clathrin-associated with the ESCRT0 component (clathrin adaptor Hrs) are observed on late endosomes during formation of multivesicular bodies. These patches, which have an unusual double-layered morphology by electron microscopy, are involved in concentrating ubiquitinated cargo for

efficient transfer to the ESCRT1-3 degradation machinery (Raiborg *et al.*, 2002).

Organelle Biogenesis

The clathrin-mediated pathways that generate lysosomes, secretory granules, dense core granules, and the storage compartment for the GLUT4 glucose transporter arise from the TGN of mammalian cells. These pathways are nucleated by the AP1 and GGA adaptors, and some involve retrograde transport from late endosomes as well as anterograde transport from the secretory pathway. The AP1 and GGA adaptors are recruited to membranes containing PI(4)P via interaction with ARF1. In the case of AP1, ARF1 binding causes a conformational change that facilitates cargo interaction, similar to that observed upon AP2-PI(4,5)P₂ interaction (Canagarajah *et al.*, 2013). Whether the GGAs function independently or in conjunction with AP1 to direct intracellular clathrin-mediated cargo traffic is not yet established.

Formation of lysosomes, secretory granules, and dense core vesicles

The majority of synthesized lysosomal enzymes are modified with mannose-6-phosphate, which is recognized by two specific receptors in mammalian cells (cation-dependent and cation-independent). These receptors are cargo for CHC17 CCVs at the TGN, which deliver the modified lysosomal enzymes to late endosomes, where they dissociate to remain in the forming lysosome, while the receptor is recycled by clathrin back to the TGN (Braulke and Bonifacino, 2009). Clathrin's role in the maturation of granules containing hormones for regulated secretion, such as insulin, is not active delivery of contents but removal of non-granule membrane components from the maturing granule (Klumperman *et al.*, 1998; Molinete *et al.*, 2001). With regard to formation of dense core vesicles containing neurotransmitters, CHC17 clathrin recruited by the AP3 adaptor may play a similar removal role in maturation. However, the self-assembling Vps41 coat protein (CHCR-containing) interacting with AP3 has been implicated in active sorting of components to the dense core granule (Asensio *et al.*, 2013).

Formation of the GLUT4 storage compartment (CHC22 clathrin)

GLUT4 is the insulin-responsive glucose transporter responsible for postprandial glucose clearance. In muscle and adipose cells, GLUT4 is packaged in vesicles that are released upon stimulation of the insulin receptor and, in the case of muscle, also in response to exercise (Bryant *et al.*, 2002). The formation of intracellular GLUT4 storage vesicles provides a reservoir of transporters that, when delivered to the PM, can generate a rapid metabolic response resulting in tissue uptake of glucose. From well-studied murine adipocyte and rat myoblast models, it has been established that CHC17 clathrin plays a role in formation of the GLUT4 storage compartment through membrane traffic from late endosomes and the TGN (Bogan, 2012). In humans, this pathway is mediated by CHC22 clathrin instead of CHC17 (Vassilopoulos *et al.*, 2009). CHC17 in human GLUT4 membrane traffic controls only endocytosis

and not intracellular sequestration. CHC22 sorting functions have been mapped to retrograde transport from late endosomes to the TGN (Esk *et al.*, 2010) and CHC22 expression levels are highest in human muscle, where this pathway contributes to GLUT4 sequestration. In muscle of insulin-resistant type 2 diabetic patients, CHC22 accumulates at the expanded GLUT4 storage compartment that results from an impaired insulin response (Vassilopoulos *et al.*, 2009). The different biochemical properties of CHC22 clathrin compared to CHC17 define specialized features of human glucose metabolism.

Clathrin Roles in Yeast and Plants

Clathrin-mediated endocytosis in yeast requires CLC and actin, as well as the Hip family protein Sla2p (Boettner *et al.*, 2012). One explanation for this requirement is that the turgor pressure of yeast cells generates an outward force on the PM that resists endocytosis, requiring CLC and actin to provide strength to the clathrin lattice (Aghamohammadzadeh and Ayscough, 2009). A known cargo for clathrin-mediated endocytosis in yeast is the pheromone receptor Ste2p, which is a GPCR, and might require CLC participation for the same reasons as needed for uptake of some mammalian GPCRs. Clathrin in yeast is also responsible for retention of proteins in the TGN, a function established by analysis of one of the first CHC mutants (Payne and Schekman, 1989). The cargo identified was the Kex2p endoprotease, needed for processing the alpha factor mating pheromone.

Arabidopsis plants have two CHC proteins and three CLCs (Baisa *et al.*, 2013). Clathrin plays a key role in maintaining the polarity of plant cells. The polarized localization of the PIN efflux carriers for auxin depends on their clathrin-mediated endocytosis and targeted recycling to the correctly polarized domain (Kania *et al.*, 2014). Although plants perform endocytosis in the context of a cell wall, the role of actin in their clathrin-mediated endocytosis is not clearly established (Baisa *et al.*, 2013).

Non-membrane Traffic Roles for Mammalian CHC17 Clathrin

Clathrin is observed associated with the mammalian mitotic spindle (Okamoto *et al.*, 2000). While initially thought to play a role in membrane traffic to and from the spindle-associated membrane-containing matrix, it is now established that clathrin's role at the spindle is independent of a membrane traffic function for clathrin (Royle, 2012). During mitosis, phosphorylation of the TACC3 protein by Aurora kinase A creates a binding site that interacts with the CHC17 terminal domain and incorporates clathrin (with associated CLCs) into a complex with the TACC3 and chTOG proteins. This protein complex binds kinetochore (K-fiber) microtubules in the mitotic spindle and, due to the trimeric nature of clathrin, stabilizes these bundled microtubules by cross-linking them. Depletion of clathrin thereby induces chromosomal dysjunction and mitotic defects. Clathrin's role at the spindle can be restored using a mutant truncated clathrin that contains the trimerized terminal domain, but is missing the proximal leg domains needed for clathrin lattice formation (Booth *et al.*, 2011).

Thus, clathrin functions as a stabilizing cross-linker in this instance. Early in mitosis the TACC3–chTOG–clathrin complex also plays a role in centrosome integrity, so that clathrin depletion induces fragmented centrosomes and formation of multipolar spindles (Foraker *et al.*, 2012). It is not yet clear how conserved is the participation of clathrin in a microtubule-stabilizing function. Clathrin has been observed at the mitotic spindle in vertebrates, *Drosophila*, and plants, but its role in yeast mitosis is yet to be clarified. It has been proposed that participation in the TACC3–chTOG complex is an evolutionarily recent function for clathrin compared to its role in membrane traffic (Royle, 2012). The discovery of this novel function for clathrin that arises from its cross-linking as opposed to polymerization capacity suggests that other such specialized roles for clathrin may be uncovered in the future.

Conclusions

1. The triskelion shape and ability of CHCs to polymerize into a lattice are the key features that enable the protein to perform its function as a vesicle coat that mediates cargo selection for transport.
2. The CLCs contribute stability and strength to the clathrin lattice through interaction with the central portion of the triskelion and through binding the Hip family proteins that connect clathrin to the actin cytoskeleton.
3. The properties conferred by CLCs expand the type and size of cargo that clathrin-coated membranes can transport and allow clathrin to play an actin-organizing function during microbial infection and cell–cell contact.
4. CHC22 clathrin, the second isoform present in humans but missing from mice, plays a key role in targeting the GLUT4 glucose transporter to its insulin-responsive intracellular storage compartment, defining a novel aspect of human glucose metabolism.
5. Participation of CHC17 clathrin (conventional isoform) in a microtubule-binding complex during mitosis contributes to stability of centrosomes and the mitotic spindle, exploiting clathrin's cross-linking properties and independent of its membrane traffic role.

Clathrin Independent Endocytosis

RG Parton, The University of Queensland, Brisbane, QLD, Australia

© 2016 Elsevier Inc. All rights reserved.

Introduction

Clathrin-mediated endocytosis is one of the best-studied processes in mammalian cell biology and is now understood in submolecular detail. Endocytosis also occurs without clathrin and in recent years it has become apparent that clathrin-independent (CI) endocytic processes are of high capacity, have crucial physiological roles, and have been exploited by many pathogens. Here the major clathrin-independent pathways will be reviewed focusing on macropinocytosis, caveolar endocytosis, and the other major clathrin-independent endocytic pathways, particularly the CLIC/GEEC (clathrin-independent carrier/glycosylphosphatidylinositol (GPI)-anchored protein-enriched early endosomal compartment) pathway.

Macropinocytosis

Definition

Macropinocytosis is the uptake of large volumes of fluid through actin-dependent protrusions of the cell surface. Macropinocytosis has been defined operationally as a pathway sensitive to the drug, amiloride, which involves the formation of large (diameter greater than 0.2 μm) vacuoles in the region of plasma membrane ruffles (Kerr and Teasdale, 2009; Swanson, 2008; Figure 1). Constitutive macropinocytic activity appears to vary greatly between different cell types, with particularly high activity in dendritic cells (Norbury, 2006). In other cells macropinocytosis can be stimulated by growth factors and active oncogenes.

Molecules

Machinery: Macropinocytosis involves the generation of circular ruffles from actin-rich plasma membrane ruffles that close to engulf large volumes of fluid. The small GTPases, Rho, Rac, and Cdc42 work together to initiate actin polymerization (Mooren *et al.*, 2012). The importance of this step can be demonstrated experimentally by the sensitivity of macropinocytosis to disruption of actin. In addition, the macropinocytosis inhibitor, amiloride, inhibits Na^+H^+ exchange, which would normally counteract a submembrane drop in pH on growth factor stimulation. In the presence of amiloride the low pH inactivates the small GTPases required for actin rearrangement (Koivusalo *et al.*, 2010). Branching actin filaments required for formation of the macropinosome are formed through the action of Arp2/3. Other molecules linked to macropinosome formation include BAR domain-containing sorting nexins (Wang *et al.*, 2010), Rabankyrin5 (Schnatwinkel *et al.*, 2004), p21-activated kinase (PAK1), and CtBP1/BARS (Liberali *et al.*, 2008). PAK1 phosphorylates CtBP1/BARS which is essential for the final closure step (i.e., scission from the plasma membrane) of the macropinosome. Mercer and

Helenius (Mercer and Helenius, 2009, 2012) have suggested a macropinocytosis 'toolbox,' a set of inhibitors and molecular targets, that can be used to test whether uptake of a particular agent uses macropinocytosis.

Cargo: By definition macropinocytosis is a pathway for uptake of large volumes of nonspecific solutes. Macropinocytosis allows for efficient sampling of large volumes of extracellular media and rapid uptake of solutes destined for degradation. In addition to these physiological roles, a number of viruses and bacteria exploit this pathway, stimulating macropinocytosis as a means to enter the cell. These include pathogenic bacteria such as *Salmonella*, *Shigella*, and mycobacteria as well as viruses such as vaccinia virus, coxsackie virus, and adenovirus (Kerr and Teasdale, 2009; Mercer and Helenius, 2009, 2012). Stimulation of macropinocytosis is an advantageous strategy for the pathogen by causing its encapsulation within a macropinosome. Interestingly, macropinocytosis appears to also be an important pathway for uptake of many artificial agents, particularly those designed for therapeutic delivery to cells. Macropinocytosis is known to contribute to the uptake of cell-penetrating peptides such as transactivator of transcription (TAT) and to a number of nanoparticle delivery systems (Gilleron *et al.*, 2013).

Carriers

Macropinosomes form when surface ruffles fuse back with the plasma membrane to encapsulate a large volume of extracellular fluid and can be over 5 μm in diameter (Figure 2). Carrier formation occurs as ruffles, sheet-like extensions of the cell surface, form crater-like structures termed cups (Swanson, 2008). To form the macropinosome the cup must close through contraction of the distal region of the cup followed by membrane fission and fusion to generate the macropinosome (for review see Swanson, 2008). Although macropinosome formation is intimately linked to and dependent on membrane ruffle formation, macropinocytosis can be inhibited without affecting membrane ruffling (Gilleron *et al.*, 2013; West *et al.*, 2000) showing that macropinosome formation is a regulated process. The importance of phosphoinositide lipids in macropinocytosis has been known for some time. Inhibition of phosphoinositide 3-kinases inhibits macropinosome formation. More recently the sequential breakdown of $\text{PI}(3,4,5)\text{P}_3$ to PI via $\text{PI}(3,4)\text{P}_2$ and $\text{PI}(3)\text{P}$ was shown to be essential for completion of macropinosome formation (Maekawa *et al.*, 2014). One effector for $\text{PI}(3)\text{P}$ was identified as the calcium-activated potassium channel, KCa3.1 , which was also shown to be required for macropinocytosis. An interesting hypothesis for the function of the channel in macropinocytosis involves $\text{PI}(3)\text{P}$ activating the channel to increase K^+ efflux, decrease cytosolic solute concentration, induce cell shrinkage and stimulate macropinocytosis (Maekawa *et al.*, 2014).

Figure 1 Clathrin-dependent and independent endocytic pathways. Scheme showing major pathways in mammalian cells together with some of the key molecules. Modified from Mayor, S., Pagano R.E., 2007. Pathways of clathrin-independent endocytosis. *Nature Reviews Molecular Cell Biology* 8 (8), 603–612.

Pathway

The majority of microscopic studies following macropinocytosis have shown that macropinosomes fuse with endosomal compartments and deliver their contents to lysosomes. This is consistent with the role of macropinocytic trafficking in the degradation of endocytosed proteins in the kidney and in immunological cells (Kerr and Teasdale, 2009). However, in other cell types separation from the endocytic pathway and refusion with the plasma membrane has been described (Hewlett *et al.*, 1994).

The trafficking pathways have been particularly well characterized in EGF-stimulated HEK293 cells. The large size of macropinosomes and the ability to stimulate formation in a synchronized manner has allowed a detailed quantitative description of their formation and maturation (Kerr *et al.*, 2006; Hamilton *et al.*, 2009). After a few minutes of stimulation macropinosomes have been formed and are associated with tubules coated in sorting nexins. These tubules rapidly depart from the forming macropinosome to fuse with more centrally located early endosomes in a microtubule-dependent fashion. Loss of these tubules, which have a high membrane area to volume ratio, causes a rapid loss of macropinosome surface area, without a major change in volume increasing the internal pressure in the macropinosome. This process is required for maturation of the macropinosome including acquisition of Rab7, a small GTPase associated with late endosomal trafficking. Concomitant with Rab7 acquisition are further changes in phosphoinositide composition with the transition from PI(3)P to PI(3,5)P₂ essential for fusion with late endosomes/lysosomes (Kerr *et al.*, 2010).

Quantitative Aspects and Dynamics

Macropinosomes can engulf a large amount of the plasma membrane as they form: a 5 μ m diameter macropinosome clearly removes a significant portion of the plasma membrane. Recycling from the macropinosome back to the plasma membrane therefore becomes an important issue and sorting nexin-labeled tubules have been estimated to remove over 80% of the limiting membrane of the macropinosome as it matures (Hamilton *et al.*, 2009). Detailed kinetics and quantitative parameters have been provided for macropinosome formation and maturation and correlated to specific endosomal markers in growth factor-treated cultured cells.

Functions

Macropinocytosis is a crucial feature of dendritic cells and macrophages. Engulfment of large volumes of the extracellular medium allows sampling of the immediate environment for foreign agents. Antigens taken up by macropinocytosis can be presented on both class I and class II major histocompatibility complex (MHC) molecules and so macropinocytosis has a crucial role in the immune system (Norbury, 2006; Sallusto *et al.*, 1995; Lim and Gleeson, 2011). Macropinocytosis has also been suggested to be a major pathway in the reabsorption of proteins from the glomerular filtrate by proximal tubule cells in the kidney based on studies of Rabankyrin5 (Schnatwinkel *et al.*, 2004). There is also increasing evidence for a role of macropinocytosis in cell migration (Gu *et al.*, 2011).

Macropinocytosis has been known for some time to be induced in cells transformed by oncogenes such as mutant

Figure 2 Morphology of caveolae, macropinosomes, and early carriers on the CLIC/GEEC pathway. Upper panel: caveolae (arrowheads) are abundant flask-shaped pits without an evident coat (compare with clathrin coated profile). Lower left panel: macropinosome (asterisk) labeled by HRP as visualized in a thick section. Adapted from [Figure 2\(c\)](#); Kerr, M.C., *et al.*, 2006. Visualisation of macropinosome maturation by the recruitment of sorting nexins. *Journal of Cell Science* 119 (Pt 19), 3967–3980. Lower right panel: CLICs labeled with an internalized toxin-peroxidase construct. Adapted from part of [Figure 1\(g\)](#); Howes, M.T., *et al.*, 2010. Clathrin-independent carriers form a high capacity endocytic sorting system at the leading edge of migrating cells. *Journal of Cell Biology* 190 (4), 675–691.

forms of K-Ras ([Bar-Sagi and Feramisco, 1986](#)). Transformed cells change their metabolic properties and become dependent on supplied amino acids for growth. Upregulation of macropinocytosis increases uptake of extracellular proteins. The intracellular degradation of the internalized proteins provides an essential amino acid supply in transformed cells ([Commisso *et al.*, 2013](#)). Thus, macropinocytosis of extracellular proteins provides an amino acid supply route for the tumor cells, making macropinocytosis a potential therapeutic target.

Caveolae

Definition

Caveolae are 50–80 nm cup-shaped pits in the plasma membrane of many vertebrate cells ([Figure 2](#)). Caveolae are extremely abundant in adipocytes, skeletal muscle cells, endothelia, and fibroblasts but undetectable in some other cell types. Caveolae are generally classified as uncoated structures as they do not possess the prominent coat structure characteristic of clathrin-coated pits. However, with specialized

electron microscopic techniques a characteristic striated coat can be visualized on the cytoplasmic face of caveolae. Caveolae are defined by their morphology and by their association with two classes of proteins, caveolins and cavins.

Molecules

Machinery: Caveolins are oligomeric integral membrane proteins that have been widely used as markers of caveolae. Three gene products exist in mammalian cells; caveolin-1 (CAV1), caveolin-2 (CAV2), and caveolin-3 (CAV3). CAV1 and CAV3 are essential for caveolar formation in non-muscle tissues and striated muscle respectively whereas CAV2 plays a facilitatory role in combination with CAV1 ([Parton and Simons, 2007](#)). Cavins are cytoplasmic proteins that work together with caveolins to generate stable caveolae. Four cavin proteins exist in mammalian cells, cavin1 (PTRF), cavin2 (SDPR), cavin3 (PRKCDP) and the muscle-specific cavin4 (MURC), forming a complex within the cytosol of mammalian cells which is recruited to the cell surface to form caveolae in conjunction with caveolins ([Hansen and Nichols, 2010](#); [Ariotti and Parton,](#)

2013). Cavins can be released into the cell in response to specific stimuli (Sinha *et al.*, 2011) but during endocytic trafficking of caveolae stay associated with the budded caveolae (Boucrot *et al.*, 2011). Budding of caveolae is dependent on the mechanical enzyme dynamin which has been localized to the neck of caveolae (Oh *et al.*, 2012, 1998; Henley *et al.*, 1998) or shown to be recruited in response to specific cargoes (Pelkmans *et al.*, 2002). The large ATPase, EHD2, negatively regulates the dynamin-dependent budding of caveolae (Morén *et al.*, 2012; Stoeber *et al.*, 2012).

Cargo: Considerable controversy remains about the specific cargo internalized through caveolae. Proposed cargo include the uncoated virus simian virus 40 (Anderson *et al.*, 1996; Stang *et al.*, 1997), bacterial toxins such as cholera toxin, and membrane proteins including the TGF-beta receptor (Di Guglielmo *et al.*, 2003), insulin receptor (Fagerholm *et al.*, 2009), integrin beta1 (Kanai *et al.*, 2014), and LRP1 (Kanai *et al.*, 2014). In very few cases has the dependence of these agents on caveolae for uptake (e.g., by comparison with cells lacking caveolae) been demonstrated. Where this has been examined in detail the agent of interest was generally still efficiently internalized in cells lacking caveolae (e.g., SV40; Damm *et al.*, 2005).

Carriers

Budded caveolae have been described in ultrastructural studies which carefully distinguished surface-connected caveolae from budded caveolae (Kirkham *et al.*, 2005). Budded caveolae showed the predicted size, vesicular morphology, and CAV1 labeling consistent with scission of individual caveolae from the plasma membrane. In addition, larger complex multicaveolar structures have been described in many cell types (Parton, 1994).

Pathway

A consensus has now emerged to suggest that caveolae fuse with the Rab5 and EEA1-positive early endosome (Boucrot *et al.*, 2011; Pelkmans *et al.*, 2004). Earlier studies suggested that a novel endosomal compartment, the caveosome, was the destination for budded caveolae (Pelkmans *et al.*, 2001). This is now thought to represent an artefactual situation due to overexpression of GFP-tagged CAV1 (Hayer *et al.*, 2010) and until further evidence is available the caveosome can be removed from caveolae-trafficking schemes (Parton and Howes, 2010). Caveolae can recycle back to the plasma membrane from the early endosome. During this cycle and after fusion with the early endosome, caveolar domains defined by a specific quantum of caveolin molecules can be detected on the limiting membrane of the early endosome (Pelkmans *et al.*, 2004). After releasing their cargo of cholera toxin, these domains can cycle back to the cell surface.

Caveolin can also be turned over via recruitment into the intraluminal vesicles of multivesicular bodies and degradation (Hayer *et al.*, 2010). This may be particularly important in cells in which there is an imbalance of caveolin and cavins, for example if caveolin is overexpressed or cavin levels are low (Hayer *et al.*, 2010; Hill *et al.*, 2008).

Quantitative Aspects and Dynamics

Caveolae can occupy over 40% of the cell surface area in adipocytes. In other cells, such as many lymphocytes (Fra *et al.*, 1994), many neurons, and kidney proximal tubule cells (Zhuang *et al.*, 2011) caveolae are undetectable. This should be taken into account when attempting to understand the endocytic functions of caveolae. In fibroblastic cell lines caveolae generally occupy between 1% and 7% of the plasma membrane surface area. In these cells, in which caveolar dynamics have been studied in some detail, total internal reflection fluorescence microscopy (TIRF) microscopy has been used to follow the dynamics of GFP CAV1 puncta (considered to be caveolae). The lifetime of individual caveolae has been shown to vary within one population with caveolar budding within seconds up to several minutes (Boucrot *et al.*, 2011). Electron microscopic studies estimated 0.5–1% of caveolae to bud within 1 minute in cultured cells (Kirkham *et al.*, 2005; Le Lay *et al.*, 2006).

Functions

Patients lacking CAV1 (and thus non-muscle caveolae) show a severe lipodystrophy, characterized by lack of adipose tissue (Garg and Agarwal, 2008). In addition, a number of muscle diseases have been linked to mutations in CAV3. The underlying cause of these conditions may be due to a loss of mechanoprotection mediated by caveolae (Sinha *et al.*, 2011). Cavins have also been linked to a number of diseases including cardiomyopathy and cancer. Caveolar endocytosis has been implicated in transcellular transport across the endothelial monolayer (Simionescu *et al.*, 2002), endocytosis of junctional components (Marchiando *et al.*, 2010; Orlichenko *et al.*, 2009), uptake of lipid microdomain components as cells detach from the substratum (del Pozo *et al.*, 2005), uptake of specific surface receptors and membrane repair (Corrotte *et al.*, 2013). The dynamic cycle of caveolar endocytosis may also serve to regulate levels of surface caveolae. For example, caveolar density is modulated as cells progress through the cell cycle by regulation of the caveolar endocytic/exocytic cycle (Boucrot *et al.*, 2011).

Clathrin- and Caveolin-Independent Micropinocytic Pathways

Definition

Unlike macropinocytosis and caveolar endocytosis, micropinocytic clathrin-independent pathways have been difficult to define in terms of morphology and specific markers. Instead, nonspecific endocytic markers, such as fluid phase markers and membrane-bound toxins, that are taken up in a clathrin- and caveolin-independent manner have generally defined clathrin-independent endocytic pathways. However, a number of proteins have now been identified as specific cargo proteins and components of the molecular machinery of these endocytic pathways as outlined below.

Molecules

Machinery: The CLIC/GEEC pathway is now the best understood clathrin-independent endocytic pathway. Endocytosis is

dynamamin-independent but is dependent on the small GTPase Cdc42 (Sabharanjak *et al.*, 2002; Chadda *et al.*, 2007), the coat protein ARF1, actin, the Rho-GAP-domain and BAR domain protein, GRAF1 (Doherty *et al.*, 2011; Lundmark *et al.*, 2008), and the lectin, galectin3 (Lakshminarayan *et al.*, 2014). Cholesterol and glycosphingolipids are integral to the function of the CLIC/GEEC pathway (Chadda *et al.*, 2007; Lakshminarayan *et al.*, 2014; Chaudhary *et al.*, 2014).

Uptake of the interleukin 2-receptor (IL2R) defines a separate endocytic pathway which differs from the above by dependence on dynamin. Key machinery proteins include RhoA, Rac1, PAK1, and PAK2 (Grassart *et al.*, 2008; Lamaze *et al.*, 2001). Endocytosis of MHC Class I appears to define a third pathway which is inhibited by ARF6 mutants (Radhakrishna and Donaldson, 1997) although recent studies have questioned the clathrin independence of this pathway (Stahlschmidt *et al.*, 2014).

Cargo: Proteins lacking signals for uptake via clathrin coated pits are internalized through clathrin-independent pathways. GPI-anchored proteins were one of the first identified CLIC/GEEC cargo proteins (Sabharanjak *et al.*, 2002) but whether there is specific concentration in clathrin-independent carriers at the plasma membrane is unclear (Bhagatji *et al.*, 2009). More recently the transmembrane hyaluronic acid receptor, CD44, was shown to be internalized via the CLIC/GEEC pathway (Lakshminarayan *et al.*, 2014; Howes *et al.*, 2010). CD44 is also associated with clathrin-independent endocytosis via the pathway involved in MHC Class I uptake and which is affected by dominant acting mutants of ARF6 (Eyster *et al.*, 2009). The boundaries between these two pathways are therefore somewhat unclear at present as other cargo proteins, such as CD98, an amino acid transporter, have also been shown to associate with both pathways (Howes *et al.*, 2010; Eyster *et al.*, 2009). Further characterization of the uptake of these and other cargo proteins is needed to resolve whether they are completely distinct or represent the same basic pathway but with slightly different characteristics in different cell types.

Recent studies have lead to a model for the formation of the CLIC/GEEC carriers and recruitment of cargo by galectin3. Galectin3 on the exterior surface of the plasma membrane binds both glycosphingolipids and cargo proteins such as CD44 and these interactions shape the plasma membrane into the tubular forms required for generating the early carrier (Lakshminarayan *et al.*, 2014). These studies demonstrate an intriguing mechanism by which endocytosis can occur without the cytoplasmic clathrin coat; early carrier formation relies on a novel extracellular membrane-shaping and cargo recruitment mechanism.

Carriers

The endocytic carriers on the CLIC/GEEC endocytic pathway were characterized through the development of an electron microscopy technique designed to identify the earliest budded structures and distinguished surface and internal vesicles (Kirkham *et al.*, 2005). This has been combined with electron tomography to yield 3D information (Howes *et al.*, 2010). Early carriers are tubular and cisternal (Figure 2) and even at the earliest stages studied (15 s) intraluminal vesicles, characteristic of later endosomal compartments, were occasionally observed. Tubular elements are less

than 50 nm in diameter and thus have a high surface area: volume ratio.

Less information is currently available on the carriers involved in the MHC class I uptake pathway shown to be disrupted by ARF6 mutants and the pathway mediating IL2R uptake.

Pathway

The CLIC/GEEC pathway converges with the clathrin-dependent endocytic pathway at the Rab5-positive early endosome (Sabharanjak *et al.*, 2002; Howes *et al.*, 2010). Early carriers acquire Rab5 and fuse with EEA1-positive early endosomes in a PI3 kinase-dependent step (Kalia *et al.*, 2006). A number of cargo proteins internalized through clathrin-independent endocytosis then diverge from the conventional endocytic cycling pathway to enter a novel recycling route. This is best studied for CD44, CD98, and CD147 (also called emmprin or basigin). These proteins enter cells via clathrin-independent endocytosis but then rapidly enter specialized recycling tubules devoid of the transferrin receptor and EEA1 (Eyster *et al.*, 2009). CD44, CD98, and CD147 avoid trafficking to lysosomes and degradation (Eyster *et al.*, 2011) and this is mediated by sorting determinants in their cytoplasmic domains. These domains interact with the microtubule and cargo binding protein Hook1 in coordination with Rab22a and microtubules (Maldonado-Báez *et al.*, 2013).

Quantitative Aspects and Dynamics

Until recently the magnitude of clathrin-independent endocytosis was difficult to ascertain because of the lack of specific markers for the pathway and still remains a controversial area (Bitsikas *et al.*, 2014). However, in immortalized mouse embryonic fibroblasts uptake through the CLIC/GEEC pathway appears to surpass uptake through clathrin coated pits (Howes *et al.*, 2010). Using a number of independent techniques including inhibition of other endocytic pathways with specific dynamin inhibitors and EM quantitation using strict morphological criteria in the absence of inhibitors it was estimated that an area equivalent to the entire plasma membrane of the cell could be endocytosed in 12–17 min in these cells, with an estimated 3000 carriers per minute (Howes *et al.*, 2010). This endocytosis must be balanced by insertion of membrane into the plasma membrane through a high capacity recycling pathway. In one study it was estimated that 40% of endocytosed fluid is regurgitated in 5 min (Chadda *et al.*, 2007).

Functions

The magnitude of the CLIC/GEEC pathway and relative nonspecificity suggests that this pathway could allow rapid remodeling of the cell surface. This is consistent with findings that when cells detach, round up and then spread when replated trafficking is via an intracellular compartment enriched in GPI-anchored proteins (Gauthier *et al.*, 2009). Ablation of CI-endocytosis or recycling on this pathway inhibits the spreading process.

One striking feature of the CLIC pathway is its polarization to the leading edge of migrating cells (Howes *et al.*, 2010). Ablation of the CLIC/GEEC pathway reversibly inhibits cell

migration. Undoubtedly with the recent tools that have just become available other cellular processes will be found to be dependent on this universal pathway. For example, recent work has linked CI-endocytosis to lumen formation in endothelia (Porat-Shliom *et al.*, 2013).

Conclusions and Perspectives

Recent work has given insights into the novel molecular mechanisms involved in endocytic carrier formation without clathrin. Caveola formation involves integral membrane proteins working together with a complex of cytoplasmic coat proteins. Formation of CLIC/GEEC carriers involves a novel mechanism of extracellular lipid and membrane protein binding on the external side of the membrane in a process that couples cargo recruitment and membrane carrier formation. Macropinocytosis differs from the above in that the carrier engulfs fluid and uses actin rearrangement as the driving force for the formation of the characteristic large macropinosome.

Recent years have seen great advances in understanding these three types of endocytic pathways but the actual number of distinct pathways is still unclear. While galectin-3 is associated with and functional in the CLIC/GEEC pathway, galectin-4 is associated with novel clathrin-independent early carriers (Lakshminarayan *et al.*, 2014). The boundaries between distinct pathways are also indistinct. Both macropinocytosis and CLIC/GEEC endocytosis can occur in regions of membrane ruffling and share some common components. There is also crosstalk between different pathways with caveolae negatively regulating CLIC/GEEC endocytosis (Chaudhary *et al.*, 2014).

Finally, the three pathways described here have been extensively characterized in cultured cells. Far less is known about these pathways in tissues *in vivo*. What is the magnitude of these pathways in different tissues in a living animal? Analysis of these pathways *in vivo* in health and in disease is a great challenge for the future but the effort will undoubtedly reap great rewards.

Overview

The balance between the internalization and recycling of proteins and lipids is crucial for control of plasma membrane composition and contributes to many cellular processes such as nutrient uptake, cell signaling, cell adhesion and junction formation, cell migration, cytokinesis, and cell polarity. The endosomal recycling pathway is composed of two main compartments, the early sorting endosome (ESE) and the endosomal recycling compartment (ERC). Early endosomes are tubulo-vesicular structures that typically assume a peripheral location in the cell, while the ERC is a collection of tubular membranes that are typically condensed around the centrosome, also known as the microtubule organizing center near the nucleus (Maxfield and McGraw, 2004). Proteins present in endosomes may be cargo such as receptors and their ligands, or they may be proteins that contribute to the shape and function of the vesicle or organelle, for example, EEA1. Indeed, the ESE matures into late endosomes (LE).

There are several mechanisms by which molecules are internalized from the plasma membrane. These mechanisms fall into two main categories: clathrin-mediated endocytosis and clathrin-independent endocytosis (CIE). In clathrin-mediated endocytosis the cytoplasmic domains of cell surface proteins are recognized by adapter proteins and packaged into clathrin-coated vesicles that are transported into the cell. CIE is an umbrella term for several modes of internalization including phagocytosis, macropinocytosis, and caveolae-mediated internalization. Regardless of the mechanism of internalization most pathways converge at the ESE, where cargo is sorted for onward transport to the degradative or recycling pathways (Grant and Donaldson, 2009).

ESEs have a pH of ~ 6.0 that promotes the uncoupling of many ligands from their receptors. This represents the first sorting step, in which the receptors remain embedded in the membrane bilayer while the ligand is released into the lumen. Most ESE are capable of accepting internalized cargo for 5–10 min, after which they undergo ‘maturation’ into LE. Maturation of ESE involves their microtubule-dependent translocation toward the cell interior, the lumen becomes more acidic, they stop fusing with newly endocytosed vesicles and they accumulate acid hydrolases. Thus cargo destined for degradation does not leave the lumen of the ESE. This is an efficient means of ‘delivering’ cargo to LE, eliminating the need for transport intermediates.

Cargo that is to be recycled back to the plasma membrane, which accounts for the majority of internalized molecules, is removed from the maturing ESE during the period of time before it translocates to the cell center. This occurs by the pinching off of narrow membrane tubules from the ESE. These tubules have a greater surface-to-volume ratio than the vesicular portion of the ESE, therefore recycled membrane is preferentially sorted away from the soluble molecules in the lumen. This is a bulk transport pathway, i.e., a membrane-

bound protein that has been recently internalized will be transported away from LE in recycling tubules. Membrane-bound proteins that are to be degraded must have specific targeting information, usually ubiquitin covalently linked to lysine residues in the cytoplasmic domain, which targets them to LE (Jovic *et al.*, 2010).

There are two main pathways for returning cargo to the plasma membrane (Figure 1). The ‘short-loop’ recycling pathway involves transport of molecules directly from the ESE back to the plasma membrane. The halftime for this pathway is ~ 2 min. The other route, the so-called ‘long-loop’ recycling pathway, involves transport back to the plasma membrane via the ERC. The ERC is a longer-lived organelle which appears to have several distinct return routes back to the cell surface. Cargos, such as the transferrin receptor, that are internalized by clathrin-mediated endocytosis are recycled back to the plasma membrane in transport carriers that are distinct from the tubular recycling endosomes that carry cargo molecules, such as sphingomyelin, which undergo CIE. Despite the fact that these two pathways are regulated by different machineries they have similar kinetics, with a $T_{1/2}$ for return to the cell surface of ~ 10 min for both routes. Glycosylphosphatidylinositol-anchored proteins are recycled back to the plasma membrane by a much slower pathway, with a $T_{1/2}$ of ~ 30 min. Cargos that enter the ERC can also be sorted for onward transport to the *trans*-Golgi network (TGN). Shiga toxin and TGN38 are examples of such cargo (Grant and Donaldson, 2009).

Polarized epithelial cells have a more complex endosomal recycling pathway. Molecules internalized from the basolateral plasma membrane enter basolateral early endosomes while molecules from the apical plasma membrane enter apical early endosomes. Cargo that is not trafficked onwards to LE, or directly recycled back to the plasma membrane of origin, are sent to a common recycling endosome (CRE), which is mildly acidic. Proteins destined for the apical plasma membrane are further sorted into an apical recycling endosome (ARE). It is unclear whether the ARE is a distinct organelle or a sub-domain of the CRE, however the ARE can be distinguished by its cup-shaped morphology, the absence of basolateral cargo such as the transferrin receptor, and a neutral pH (Thompson *et al.*, 2007).

Many ‘nonclassical’ endosomal recycling pathways can be found in specialized cells. In mature neurons recycling endosomes localize to the base of dendritic spines and play a role in long-term potentiation (LTP). LTP is one of the major cellular mechanisms that underpin learning and memory and relies on the rapid insertion of glutamate receptors into the spine and spine growth. The recycling endosomes serve as local stores of membrane and glutamate receptors and stimuli that induce LTP result in the rapid translocation of recycling endosomes into spines (Kelly *et al.*, 2011).

In fat and muscle cells GLUT4 is the major glucose transporter, and controlling the amount of GLUT4 on the surface of these cells regulates the amount of glucose they internalize.

Figure 1 Schematic depiction of the endosomal recycling pathway. The localization of the Rab GTPases that function along this pathway is indicated. ESE, early sorting endosome; ERC, endosomal recycling compartment; TGN, *trans*-Golgi network.

GLUT4 is found in the ERC and TGN, but in the absence of insulin the majority of GLUT4 is stored in specialized vesicles called GLUT4 storage vesicles (GSV), or insulin responsive vesicles. In low insulin conditions GLUT4 idly cycles between these intracellular compartments with a small fraction reaching the plasma membrane at any point in time. Following a meal, the pancreas secretes insulin into the bloodstream which binds to its receptor on the surface of myocytes and adipocytes activating the PI-3-kinase/Akt pathway, leading to a rapid translocation of GLUT4-containing GSVs to the plasma membrane. This results in a 10- to 30- fold increase in the amount of glucose taken up by these cells. It is currently believed that GLUT4 undergoes clathrin-mediated endocytosis and is transported from the ESE to the ERC. In the absence of insulin GLUT4 is sorted from the ERC to GSVs, with a small fraction going directly from the ERC to the plasma membrane. However, in the continual presence of insulin it recycles back to the plasma membrane in vesicles that also contain the transferrin receptor and are distinct from GSVs (Stockli *et al.*, 2011).

Endosomal recycling is a highly regulated process and requires large protein machineries to ensure that cargo reaches the right destination at the right time. Defects in components of these machineries can have severe consequences for the cell and lead to a wide range of diseases including absorption disorders such as hemochromatosis, many neurological diseases, cancer, intestinal disorders such as microvillus inclusion disease, metabolic disorders such as Niemann–Pick disease, osteoporosis, and many others. Furthermore, many bacterial and viral pathogens subvert components of the endosomal recycling pathway during their infection cycle (Puertollano, 2006).

Key regulators of the endosomal recycling pathways are members of the Rab family of small GTPases. Humans have over sixty Rabs and they constitute the largest branch of the Ras superfamily of small GTPases. Some are expressed

ubiquitously while others are tissue-specific. Each membrane-bound compartment is typically associated with one or more Rabs. They are molecular switches that control all aspects of intracellular transport including vesicle budding, uncoating, transport, tethering, and fusion. As their name suggests they bind to guanine-nucleotides and cycle between a GTP-bound active conformation during which they recruit a diverse range of ‘effector’ proteins, and a GDP-bound inactive conformation which is predominantly cytosolic. They mediate, or ‘effect,’ their transport functions through the effector proteins they recruit when in their active conformation. Effectors include motor proteins, and proteins involved in vesicle formation, tethering and membrane fusion. GTP-bound Rabs can also recruit proteins involved in phospholipid synthesis and can directly bind to cargo proteins (Kelly *et al.*, 2012).

Several accessory proteins regulate the Rab GTPase cycle. A GTPase-activating protein stimulates the intrinsic GTPase activity of the Rab to promote the hydrolysis of bound GTP to GDP. A GDP-dissociation inhibitor (GDI) binds to the GDP-bound Rab and extracts it from membranes by interacting with the geranylgeranyl lipid moieties that are attached to two cysteines at the carboxy-terminus of the Rab. The GDI also prevents the dissociation of the GDP. A RabGEF (GDP/GTP exchange factor) displaces the GDI and catalyzes the exchange of GDP for GTP allowing the cycle to start again.

In this article we will discuss in detail the Rab GTPases that have been implicated in the transport of cargo via the ESE and the ERC to the plasma membrane (see Figure 1).

Rab4 and the ‘Short-Loop’ Recycling Pathway

The majority of Rab4 resides on the ESE, with a minor pool also localizing to the ERC (Sonnichsen *et al.*, 2000). There are two Rab4 isoforms, A and B, which are both ubiquitously expressed and have been implicated in the recycling of cargo

directly to the cell surface from the ESE in the 'short-loop' recycling pathway (van der Sluijs *et al.*, 1992; McCaffrey *et al.*, 2001; Perrin *et al.*, 2013). The trafficking of the β_2 -adrenergic receptor, membrane-type 1 matrix metalloprotease (MT1-MMP), the oxytocin receptor, the mu-opioid receptor, the transferrin receptor and the Fc receptor (FcRn) have all been shown to involve Rab4. Both Rab4 isoforms have also been implicated in the transport of GLUT4 in adipocytes (Mari *et al.*, 2006; Kaddai *et al.*, 2009). Several Rab4 effector proteins have been identified such as the dynein light intermediate chain (Bielli *et al.*, 2001) and syntaxin 4 (Li *et al.*, 2001). Rab4 also shares effectors with several other Rabs including Rabaptin-5 (Vitale *et al.*, 1998), Rabenosyn-5 (de Renzis *et al.*, 2002), and RUFY1 (Fouraux *et al.*, 2004), which it shares with Rab5. D-AKAP2 and RCP interact with Rab4 and Rab11 (Eggers *et al.*, 2009; Lindsay *et al.*, 2002), and RUFY1 also interacts with Rab14 (Yamamoto *et al.*, 2010).

Rab4 has recently been reported to coordinate the formation of the tubular subdomains of the ESE that give rise to carrier vesicles targeted to various intracellular locations including the plasma membrane and the ERC. It does this by orchestrating the formation of a GTPase cascade on the tubules. Rab4 initiates the recruitment of Arl, another class of small GTPase, which in turn recruits the Arf GEFs BIG1 and BIG2. These GEFs then locally activate Arf1 and Arf3, which in turn recruit adapter proteins that are required for cargo capture and carrier vesicle formation (D'Souza *et al.*, 2014).

Rab11 and the Endosomal Recycling Compartment

Rab11 is the best-characterized Rab that functions in the endosomal recycling pathway. The Rab11 subfamily has three members, Rab11A, Rab11B and Rab25 (also known as Rab11C). Rab11A is abundantly expressed in most tissues, Rab11B is expressed widely but not as abundantly as Rab11A, and Rab25 expression is restricted to epithelial tissues. Rab11 is primarily localized to the ERC in most cell types and it regulates recycling from this compartment (Ullrich *et al.*, 1996). Rab11 has also been observed at the TGN and on post-Golgi vesicles suggesting that it functions at the interface between the endosomal and exocytic pathways. It has been implicated in the transport of a wide variety of cell surface proteins including the EGF receptor, E-cadherin, a number of G-protein coupled receptors such as rhodopsin and the β_2 -adrenergic receptor, the AMPA receptor, the Toll-like receptor 4, and the $\alpha 5 \beta 1$ integrin. It influences many cellular processes including neurotransmission, cytokinesis, ciliogenesis, directed cell migration, and development.

Rab11 Effector Proteins

GTP-bound Rab11 recruits a number of effector proteins, key among these are the members of the Rab11-FIPs (Rab11-Family of Interacting Proteins). The Rab11-FIPs are a family of five proteins that all have a highly conserved Rab11-binding domain at their carboxy-termini. The FIPs can be subdivided into two classes. The class I FIPs include RCP (also known as FIP1C), FIP2, and FIP5 (also known as Rip11) and have a C2 phospholipid-binding domain near their amino-termini

which binds phosphatidic acid and PI(3,4,5)P₃ (Lindsay and McCaffrey, 2004). The class II FIPs, FIP3 and FIP4, lack the C2 domain but have EF-hand calcium-binding motifs, suggesting that their function is regulated via calcium signaling. Another key Rab11 effector is the exocyst, an eight subunit complex (Sec15, Sec10, Sec8, Sec84, Sec5, Sec6, Sec3, and Exo70) that tethers transport vesicles to specific regions of the plasma membrane. Exo70 and Sec3 (by analogy to its yeast homolog) bind PI(4,5)P₂ and the TC10 small G protein at the plasma membrane, thereby providing the means to target the exocyst to specific subdomains of the plasma membrane. Rab11-GTP binds directly to Sec15 (Zhang *et al.*, 2004) and this interaction may nucleate the assembly of the exocyst complex on Rab11-positive transport carriers. The exocyst is involved in most, if not all, cellular processes influenced by Rab11.

Rab11 Binds Motor Proteins

Rab11 also binds to a number of motor protein complexes, thus facilitating its bidirectional transport along microtubules and actin filaments. Myosin Vb was the first motor protein identified to interact with Rab11 (Lapierre *et al.*, 2001). It is an actin-based motor protein that mediates short-range transport along actin filaments. Rab11-GTP binds directly to the carboxy-terminal globular tail domain of myosin Vb, and Rab11 has since been found to interact with the same domain of its close relative myosin Va (Roland *et al.*, 2009). The Rab11-myosin V interaction mediates the rapid translocation of recycling endosomes into dendritic spines during synaptic plasticity (Correia *et al.*, 2008; Wang *et al.*, 2008), and the tethering and possible short-range transport of Rab11-positive vesicles at the periphery of non-specialized cells (Lindsay *et al.*, 2013).

Rab11 has also been reported to bind to both plus-end and minus-end directed microtubule motor protein complexes. To date, such interactions have been found to be indirect and occur via an intervening or linker protein. For example, FIP3 binds to the dynein light intermediate chain and acts as a bridge between Rab11 and the dynein motor complex (Horgan *et al.*, 2010). Dynein is a minus-end directed motor and its association with Rab11 facilitates the transport of cargo from the ESE to the ERC. Rab11 also associates with the plus-end directed kinesin 5A (KIF5A) via an interaction with the neuronal protein protrudin (Matsuzaki *et al.*, 2011). The Rab11-protrudin-KIF5A complex plays a role in neurite formation in neurons, and overexpression of protrudin or KIF5A induces the formation of protrusions in non-neuronal cells. A unique feature of this complex is that protrudin interacts with the GDP-bound form of Rab11. Rab11 also interacts indirectly with kinesin-2 via FIP5/Rip11 (Schonteich *et al.*, 2008), and this complex delivers vesicles to the cleavage furrow during apical lumen formation, a key step in epithelial morphogenesis of tubular organs (Li *et al.*, 2014).

Rab11 in Cell Division

Rab11 and its effector FIP3 have been implicated in cytokinesis. Cytokinesis is the final stage of mitosis in which the cytoplasm of a parent cell is divided into two daughter cells. A necessary step for the completion of cytokinesis is the

delivery of membranes to the cleavage furrow, and recent work has demonstrated that an important source of this membrane is endosomes from the recycling pathway. Both Rab11 and FIP3 localize to the cleavage furrow during cytokinesis (Horgan *et al.*, 2004), and RNAi-mediated knockdown of FIP3 results in cytokinesis defects and a failure of cells to undergo abscission (Wilson *et al.*, 2005). FIP3 also binds to Arf6, another small GTPase that is enriched at the cleavage furrow and binds to the Sec10 subunit of the exocyst complex. It has been postulated that a combination of the Rab11 association with Sec15 and the FIP3 association with Arf6 serve to target Rab11: FIP3-endosomes to the cleavage furrow during cell division (Simon and Prekeris, 2008). Recent work has demonstrated that FIP3-endosomes contain several Rac/Rho and actin regulators. The fusion of these endosomes with the plasma membrane surrounding the intercellular bridge (ICB) causes localized actin depolymerization which results in the thinning of the ICB to less than 100 nm, a process called secondary ingression. This allows the recruitment of further machinery (the ESCRT complex) that facilitates the abscission of the two daughter cells (Schiel *et al.*, 2012).

The Role of Rab11 in Synaptic Transmission

Rab11 regulates neuronal migration and maturation through its role in transporting N-cadherin (Kawauchi *et al.*, 2010), and as mentioned above the Rab11-protrudin-KIF5A complex is involved in neurite formation. *Drosophila melanogaster* embryos with homozygous Rab11 mutants display disorganized and misrouted embryonic axons (Bhuin and Roy, 2009). Overexpression of Rab11 restores synaptic dysfunction due to the expression of mutant huntingtin (htt) protein in a *Drosophila* model of Huntington's disease (Richards *et al.*, 2011; Steinert *et al.*, 2012). Thus Rab11 has an important role in nervous system development, and the observation that Rab11 is present on synaptic vesicles and is involved in mediating the transport of recycling endosomes into stimulated dendritic spines indicates that it is also involved in synaptic transmission in mature neurons.

Rab11 and Cancer

Rab25 (Rab11C) has been implicated in cancer and is unique among the Rab GTPases in that it has a GTP-binding site that is likely to render it constitutively-active *in vivo*. It has been reported to be both an oncogene in aggressive breast and ovarian cancer (Cheng *et al.*, 2004), and a tumor-suppressor gene in colon cancer (Nam *et al.*, 2010). Cheng *et al.* reported that Rab25 was upregulated at the DNA, mRNA, and protein levels and that this correlates with reduced survival of breast and ovarian cancer patients. They also demonstrated that overexpression of Rab25 in ovarian cancer cell lines increased several of the hallmarks of cancer (cell proliferation, resistance to apoptosis, anoikis, anchorage-independent growth). Rab25 expression also correlates with histological grade in patients, making it a useful clinical biomarker for ovarian cancer (Sheach *et al.*, 2009). While Rab25 overexpression can clearly be correlated to ovarian cancer aggressiveness, the situation is not as clear for breast cancer. Rab25 loss has been observed in a number of breast cancer cell lines (Cheng *et al.*, 2006, 2010).

It has recently been proposed that Rab25 functions as an oncogene in hormone receptor-positive breast cancers and as a tumor-suppressor in estrogen receptor-negative breast cancers (Mitra *et al.*, 2012). Decreases in Rab25 expression have also been observed in colon cancer patients, and this loss was associated with poorer patient outcome (Nam *et al.*, 2010). These contradictory results suggest that the role of Rab25 in cancer progression is highly context dependent and is likely to depend on the repertoire of Rab25-interacting proteins expressed by different cell types. Furthermore, Rab25 itself has been reported to control the expression of a number of gene transcripts. Knockdown of Rab25 leads to the loss of α_5 -integrin mRNA (Krishnan *et al.*, 2013), suggesting that one of the ways Rab25 may function as a tumor suppressor is by impacting upon the expression of integrins.

Our knowledge of how Rab25 functions mechanistically in cancer has been aided greatly by insights from the laboratory of Jim Norman at the Beatson Institute, Glasgow. The key features of cancer are dysregulated cell proliferation and increased migratory behavior of cancer cells, which can lead to invasion of healthy tissue and metastatic dissemination. Jim Norman and coworkers have shown that Rab25 binds directly to the β_1 integrin and promotes cell migration by transporting $\alpha_5\beta_1$ integrin-containing vesicles to the pseudopodial-tip of migrating ovarian cancer cells (Caswell *et al.*, 2007), and they subsequently showed that the Rab11 effector, RCP, is also involved in the transport of $\alpha_5\beta_1$ integrin to the leading edge of migrating cells (Caswell *et al.*, 2008). Recently they demonstrated that Rab25 also retrieves integrins that have been targeted for degradation from LE/lysosomes and transports them to the plasma membrane (Dozynkiewicz *et al.*, 2012).

Other Rabs of the Endosomal Recycling Pathway

Rab4 and Rab11 are the best studied Rabs that participate in endosomal recycling, however several other Rabs have also been implicated in this pathway. Rab8 is involved in the transport of post-Golgi transport carriers from the TGN to the plasma membrane, however in polarized cells some cargo proteins are transported to the plasma membrane via the ERC. Rab8 localization sometimes overlaps with Rab11, suggesting that these two Rabs can function at the intersection of the biosynthetic and recycling pathways. Indeed, Rab8 and Rab11 share a number of effector proteins including myosin Va (Roland *et al.*, 2009; Lindsay *et al.*, 2013) and myosin Vb (Roland *et al.*, 2007). Rab8 and Rab22A are also involved in the recycling of cargo, that has entered the cell by CIE, in tubular recycling intermediates (Sharma *et al.*, 2009; Hattula *et al.*, 2006; Weigert *et al.*, 2004). Another Rab that bridges transport between the TGN and the ERC is Rab13 (Nokes *et al.*, 2008). One of the cargos that Rab13 transports is the tight junction protein occludin (Morimoto *et al.*, 2005). Rab21 localizes to the ESE and is involved in β_1 -integrin trafficking (Pellinen *et al.*, 2006). Rab17 is an epithelial-specific Rab and its expression is induced during cell polarization (Lutcke *et al.*, 1993). It localizes to the ARE and is involved in regulating the transcytosis of cargo from the basolateral to apical membranes (Zacchi *et al.*, 1998; Hunziker and Peters, 1998). Rab14 is ubiquitously expressed and localizes to the endosomal

recycling pathway and to some extent the TGN (Junutula *et al.*, 2004). Interestingly, as is the case for many Rabs involved in the regulation of endosomal trafficking Rab14 interacts with effectors of Rab4 and Rab11. Specifically Rab14 interacts with RUFY1, a Rab4 effector (Yamamoto *et al.*, 2010), and with the class I Rab11-FIPs (Kelly *et al.*, 2009; Lindsay *et al.*, 2002). A recent report has localized Rab14 to an intermediate compartment between the ESE and the ERC, from which it transports the ADAM10 protease to cell–cell junctions in migrating cells. ADAM10 cleaves N-cadherin, an integral component of adherens junctions. In Rab14-depleted cells ADAM10 transport to the adherens junctions is inhibited resulting in the inhibition of cell–cell junction disassembly, since N-cadherin cannot be cleaved, and this leads to reduced cell migration (Linford *et al.*, 2012).

Rab35 localizes to membranes throughout the endosomal recycling pathway including the plasma membrane, ESE, and tubular recycling compartment intermediates. It regulates a direct recycling pathway, and also plays a role in cytokinesis (Kouranti *et al.*, 2006). Rab35 also regulates the actin cytoskeleton (Zhang *et al.*, 2009), and localizes to synaptic vesicles in *Drosophila* (Uytterhoeven *et al.*, 2011).

Intracellular Pathogens Subvert the Function of Rab GTPases

The normal host defense for protecting cells during infection by bacterial pathogens is to transport pathogen-containing vacuoles (PCV) to lysosomes for degradation. This pathway requires many Rab GTPases to coordinate the transport of the PCVs from an early phagocytic compartment to a Rab5-positive endosomal compartment, their subsequent shuttling through a Rab7-positive late endosome and onward transport to the lysosome. Studies on latex bead-containing phagosomes in mouse macrophages have implicated up to 40 different Rabs in this process (Stein *et al.*, 2012).

In order to evade degradation many pathogens hijack Rab protein function. They do this by expressing bacterial effectors, a diverse range of proteins that can act as receptors for Rab GTPases, or as enzymes that posttranslationally modify Rab proteins or modify the endosomal membrane lipids required by the Rabs. Bacterial effectors subvert Rab function in order to direct pathogen transport to specific intracellular locations and to monopolize host vesicles in order to facilitate their growth and differentiation. Effector expression is temporally and spatially regulated and multiple factors may act in concert to hijack Rab function. Furthermore, bacterial pathogens can modulate the expression of Rab GTPases upon infection of their hosts (Seixas *et al.*, 2012).

Some intracellular pathogens infect more than one cell type in order to gain access to the host cell machinery to facilitate their growth and differentiation. Some pathogens utilize phagocytic cells such as macrophages, for example, *Legionella pneumophila* and *Mycobacterium tuberculosis*, while others infect non-phagocytic cells and enter the cell by receptor-mediated endocytosis, lipid raft mediated internalization, or by modulation of the actin cytoskeleton through Rho family GTPases. *Salmonella enterica* invades intestinal epithelia and *Helicobacter pylori* specifically infects mucosal epithelia.

Irrespective of the cell type the following intracellular pathogens all modulate the transport of their vacuoles by subverting the function of the membrane trafficking machinery in order to evade degradation in lysosomes – Chlamydiae, *H. pylori*, *L. pneumophila*, Mycobacteria, *Pseudomonas aeruginosa*, and *S. enterica*.

A multistep process, involving a series of host-bacterial protein interactions that modulate Rab activity, is required to establish an appropriate intracellular niche for an invading pathogen to grow and divide. These steps include the inhibition of PCV transport along the degradative pathway, transport of the PCV to appropriate intracellular sites for bacterial growth and differentiation, modulation of cell signaling, and the recruitment of host vesicles that contain the proteins and lipids required to modify the PCV and provide nutrients for growth.

Chlamydia trachomatis is a well studied bacterial pathogen that subverts the function of Rab GTPases for its own ends. It is the most common sexually transmitted bacterium in the Western world and left untreated *Chlamydia* infections can lead to blindness. *Chlamydia trachomatis* enters host mucosal epithelial cells or macrophages and establishes a membrane-bound vacuole called an inclusion, in which it spends its entire lifecycle. Several Rab proteins from the endosomal recycling and biosynthetic pathway (Rab1, Rab4, Rab6, Rab11, and Rab14) have been localized to the inclusion. Unsurprisingly, Rabs involved in the degradative pathway (Rab5, Rab7, and Rab9) are not found on the inclusion body. Rab interacting proteins such as FIP2, but not the other FIP family members, also localize to the inclusion (Leiva *et al.*, 2013). Chlamydiae express a group of coiled-coil proteins called Incs that are inserted into the inclusion membrane with a domain exposed to the cytosol and are believed to be key factors involved in subverting Rab function. Indeed, the Inc protein CT229 binds directly to GTP-bound Rab4. Another such protein is the immediate early gene product CT147. It is a 162 kDa protein that shares strong structural homology with EEA1, a Rab5 effector that mediates the tethering and Rab5-dependent fusion of endosomes. CT147 lacks the Rab5 binding domain that is present in EEA1 and it has been proposed that in chlamydial infected cells it may function to tether endosomes but prevent their fusion, thus providing a means for chlamydial endosomes to avoid fusion with lysosomes (Belland *et al.*, 2003). Rab6, Rab11, and Rab14 are believed to play a role in the transport of sphingolipids to the inclusion as their depletion hinders the maturation of *C. trachomatis* and reduces the yield of infectious particles (Damiani *et al.*, 2014). See Stein *et al.* (2012) for a comprehensive review of other bacterial pathogens that hijack Rab function.

A number of viruses have also been found to subvert the function of Rab GTPases belonging to the endosomal recycling pathway. Recently it was shown that the HIV-1 retrovirus utilizes Rab14, and its effector RCP, to transport the HIV envelope glycoprotein complex to microdomains of the plasma membrane where they will be incorporated into HIV-1 particles (Qi *et al.*, 2013). The herpes simplex virus-1 is endocytosed from the plasma membrane and transported to the ERC. Rab11-depletion reduces virus yield in infected cells indicating that it is involved in HSV-1 morphogenesis (Hollinshead *et al.*, 2012). Rab11 is also involved in Influenza A virus

morphogenesis and budding (Bruce *et al.*, 2010). Both the respiratory syncytial virus (the most common cause of lower respiratory tract illness in children) and HIV-1 'piggy back' on myosin Vb in order to be transported to the plasma membrane (Brock *et al.*, 2003; Varthakavi *et al.*, 2006).

Summary

The endosomal recycling pathway plays a critical role in determining how cells communicate with the 'outside world' by regulating the protein and lipid composition of the plasma membrane. A number of Rab GTPases have been found to play key roles in coordinating the spatiotemporal transport of cargo through this pathway.

It is becoming increasingly clear that endosomal recycling does not occur on a single autonomous transport route but rather involves trafficking along a pathway that is intersected by components of other pathways including the biosynthetic and degradative pathways.

Defects in endosomal recycling can have severe consequences for the cell, which may lead to the development of a diverse range of catastrophic diseases including cancer. Furthermore, intracellular pathogens have learned to subvert the function of components of the endosomal recycling pathway to facilitate their own growth and differentiation.

A greater understanding of the molecular mechanisms involved in regulating endosomal recycling will not only lead to further insights into the functioning of normal cells but will also lead to a greater understanding of the etiology of diseases ranging from neurodegenerative disorders to cancer, as well as pathogenic bacterial and viral diseases. Such findings will likely lead to the identification of new targets for therapeutic intervention.

Endosome to Lysosome Transport

C Buccì and M Stasi, University of Salento, Lecce, Italy

Introduction

Endocytic cargo internalized from the plasma membrane to early endosomes (EEs) has to be transported to late endosomes (LEs) and then to lysosomes in order to be degraded. The endosome to lysosome pathway consists in a complex carefully regulated series of events important to control degradation of molecules. Different cellular pathways depend on this transport. For instance membrane signaling receptors, such as epidermal growth factor receptor (EGFR), are activated by ligand binding and, as they execute their function, their stimulation must be reduced in order to prevent aberrant signaling. Indeed, termination of these signaling pathways is often mediated by downregulation of membrane receptors accomplished by targeting them to degradation compartments (Ceresa and Schmid, 2000). Notably, alterations in one or more steps of endosome to lysosome transport determine deregulation of cellular functions and are causative of several diseases, thus demonstrating the importance of this pathway. For instance, alterations of protein sorting to lysosomes cause mucopolipidosis II, also called Inclusion-cell (I-cell) disease (Olkonen and Ikonen, 2006).

Endocytosed cargo is delivered to endosomes where proteins destined for degradation are sorted and delivered to lysosomes. Sorting mechanisms for correct cargo shipment to lysosomes take place both in EEs, where membrane proteins are internalized in intraluminal vesicles destined to lysosomes, and in LEs, where hydrolases incoming from Golgi compartment are delivered. Maturation of EEs is a crucial step, which occurs in a short time and involves several steps, including acidification and modification of endosome membrane and microenvironment composition.

Several key regulators of these processes have been identified and among them a crucial role is played by Rab proteins, that coordinate virtually all steps of this pathway, and by molecular motors, such as dynein and kinesins that are responsible for movement of vesicles and organelles. Although many players in this pathway have been identified and their functions unraveled, several mechanisms underlying this pathway remain poorly understood and even definitions of endocytic structures are not completely clear. This is due to the lack of sufficient evidences and difficulties in the interpretation of a wide range of heterogeneous data. Indeed, the mechanism of transport of materials between endosomes and lysosomes is still controversial and several models about the biogenesis and the maturation of endosomes and lysosomes have been proposed. These models include maturation of endosome to lysosome, vesicular transport or kiss and run fusion between endosomes and lysosomes, and complete fusion between endosomes and lysosomes in order to form a hybrid organelle (Luzio *et al.*, 2007).

Here we describe each step of the endosome to lysosome transport, illustrating the mechanisms that control these processes.

Endocytic Vesicles and Early Endosomes

Cellular internalization of fluids, solutes, proteins, and plasma membrane components such as receptors occurs via endocytosis. The most characterized mechanism that drives endocytosis is the clathrin-dependent pathway (Conner and Schmid, 2003). In this pathway, the clathrin adapter protein 2 (AP2) complex recognizes tyrosine or dileucine motifs present in the cytoplasmic domain of cell-surface proteins directing them into clathrin-coated pits that pinch off the plasma membrane to form clathrin-coated vesicles (Kirchhausen, 1999). Endocytic vesicles also arise from clathrin-independent pathways such as, for instance, caveolar, GPI-enriched early endosomal compartments GEEC- and ARF6-dependent pathways (Conner and Schmid, 2003; Mayor and Pagano, 2007). Incoming materials deriving from clathrin-dependent or independent endocytosis are then delivered to EEs (Conner and Schmid, 2003; Mayor and Pagano, 2007; Figure 1).

EEs are tubulovesicular structures involved in the sorting of internalized molecules and thus also called sorting endosomes. Their volume and tubular membrane extension are relatively small until they receive endocytic vesicles. In a short period of time (5–15 minutes) EEs accept and accumulate cargo coming from vesicles. Membranes, solutes and fluids arrived into EEs are then recycled to the plasma membranes directly or via perinuclear recycling endosomes or, alternatively, are delivered to LEs and lysosomes for degradation (Luzio *et al.*, 2007; Figure 1). Delivery of endocytosed materials to lysosomes for degradation occurs after progressive acidification of endosomal organelles, formation of multi-vesicular bodies (MVBs) and LEs, recruitment of lysosomal hydrolases from Golgi, positioning of LEs in the perinuclear region and sorting of proteins destined for degradation. Importantly, recent findings demonstrate that fission of recycling tubules in EEs is important for subsequent acidification and maturation, including endosome motility, perinuclear localization, and degradation of proteins (Mesaki *et al.*, 2011; Figure 1).

Biogenesis of MVBs and Cargo Sorting

MVBs are organelles characterized by the accumulation of vesicles in their lumen; material destined for degradation compartments is delivered to MVBs and then reaches lysosomes. MVBs are often considered as newly formed LEs derived from maturation of EEs, but, according to another model, they are defined as transporter intermediates between early and late endosomes (Gruenberg and Stenmark, 2004). MVBs move from the periphery to the center of the cell along microtubules, and mature in LE; when MVBs have lost all recycling proteins and have acquired all the molecules and the characteristics indispensable for fusion (directly or via kiss and

Figure 1 Endosome maturation. Vesicles derived from clathrin-dependent or independent endocytosis fuse with early endosomes (EEs). Membrane cargo destined for degradation is sorted in ILVs and delivered to lysosomes. Endosome to lysosome transport includes different maturation steps, comprising progressive acidification, MVBs formation, inclusion of material incoming from TGN and fusion of LEs with lysosome. During maturation, organelles move along microtubules from the periphery to the perinuclear region of the cell. Progressive acidification of organelles is represented by gradual color change from yellow (almost neutral pH, in EEs) to red (more acidic pH, in LEs, endolysosomes and lysosomes).

Figure 2 MVBs biogenesis. Endocytosed ubiquitylated receptors (e.g., EGFR) destined for degradation are delivered to EEs, where Hrs recognizes ubiquitin residues and promote ILV formation. When material destined for degradation is sorted in ILVs, MVBs bud from EEs and then detach by means of annexin-II. As described in the text, ESCRT machineries are responsible for this process.

run mechanisms) with lysosome, they are called LEs (Gruenberg and Stenmark, 2004; Woodman and Futter, 2008).

The mechanism that guides the biogenesis of MVBs is not yet completely clear and requires the sequential action of endosomal sorting complex required for transport (ESCRT) machineries (Figure 2). Membrane proteins destined for degradation in lysosomes are mono-ubiquitylated and then recognized by the hepatocyte growth factor receptor-regulated tyrosine kinase substrate (Hrs) that, acting with the signal-transducing adapter molecule (STAM) and binding to

phosphoinositol-3-phosphate (PI(3)P), sorts proteins into clathrin-coated microdomains of EEs delivering them to the degradative pathway (Jovic *et al.*, 2010). The events involving clathrin, the STAM-Hrs complex, also called ESCRT-0, and the signaling of PI(3)P represent the first step in the transition from EEs to MVBs involving invagination and formation of intraluminal vesicles (ILVs) (Gruenberg and Stenmark, 2004; Falguières *et al.*, 2009; Williams and Urbé, 2007). Hrs plays an essential role in recruiting ESCRT-I to endosomes (Bache *et al.*, 2003). ESCRT-I in mammalian cells is composed of TSG101,

VPS28, VPS37A-D, and of the orthologue of the yeast Mvb12 (Williams and Urbé, 2007). TSG101 regulates the maturation of EEs in MVBs controlling the formation of stable vacuolar domains (Razi and Futter, 2006). ESCRT-I recruits in turn ESCRT-II that, in mammalian cells, is composed of EAP30, EAP20 and EAP45 (Williams and Urbé, 2007). Both ESCRT-I and ESCRT-II, as well as Hrs, contain ubiquitin binding domains and recognize ubiquitylated proteins (Hurley, 2008). The last ESCRT complex is ESCRT-III and it is composed soluble monomers (CHMP-1, CHMP-2, CHMP-3, CHMP-4, CHMP-5, and CHMP-6) that assemble on the endosomal membrane forming an insoluble array (Williams and Urbé, 2007; Hurley, 2008). ESCRT-II recruits ESCRT-III by interaction between EAP-20 and CHMP-6 while CHMP-6 has been demonstrated to regulate cargo sorting (Yorikawa *et al.*, 2005). ESCRT-III complex recruits deubiquitinating enzymes (e.g., AMSH) that remove ubiquitin moieties after sorting and before degradation; this step is thought to be the last crucial step for the entry of cargoes in ILVs (Williams and Urbé, 2007; Stuffers *et al.*, 2009a). ESCRT-III also mediates membrane invagination, concentrates cargoes in MVBs and could play a role in fusion of MVBs with LEs (Babst *et al.*, 2002; Stuffers *et al.*, 2009a; Adell *et al.*, 2014). Afterwards this complex is disassembled by VPS4, an AAA + ATPases (Williams and Urbé, 2007).

Interestingly, degradation of membrane receptors is regulated by a feedback control mechanism mediated by the ESCRT itself. Indeed, ESCRT-I components are delivered together with the cargo to lysosomes after endosomal sorting in ILVs and this event prevents collateral degradation of surface receptors (Malerød *et al.*, 2011). Thus, stimulation of degradation of a specific membrane receptor causes also downregulation of ESCRT-I components inducing transient resistance to degradation of other membrane receptors (Malerød *et al.*, 2011).

Recent findings suggest that alternative ESCRT-independent mechanisms for formation of ILVs coexist in mammalian cells with the ESCRT-dependent one (Stuffers *et al.*, 2009b). These alternative pathways are driven by lipids comprising lysobisphosphatidic acid (LBPA), ceramide and phosphoinositol-3,5-bisphosphate (PI(3,5)P₂) that spontaneously trigger the formation of ILVs by acting with their interactors (Woodman and Futter, 2008).

Several other proteins contribute to the formation of MVBs. One example is represented by SNX-3 and SNX-12, two members of sorting nexins (SNXs) proteins that function in sorting and invagination of ILVs within MVBs (Pons *et al.*, 2008, 2012). Also the Rab-interacting lysosomal protein (RILP), an effector of the small GTPase Rab7, participates at the biogenesis of MVBs. Indeed, it was found to interact with the EAP-30 and EAP45 subunits of ESCRT-II and to be responsible for ILVs formation (Progida *et al.*, 2006, 2007; Wang and Hong, 2006). The detachment of newly formed MVBs is then regulated by annexin-II that is associated to the early endosomal membrane probably by a cholesterol-dependent mechanism (Gruenberg and Stenmark, 2004; Figure 2).

Late Endosomes

When MVBs form from EEs, they mature and move to the perinuclear region of the cell where they fuse with each other

to form larger bodies that in turn can fuse with lysosomes in order to assure the degradation of transported proteins (Gruenberg and Stenmark, 2004; Huotari and Helenius, 2011). MVBs and LEs are morphologically different: MVBs are spherical, with a diameter of 400–500 nm, while LEs are larger, more pleiomorphic than MVBs and have a different composition in lipids and proteins. LEs are characterized by the presence of numerous ILVs, of lysosomal-associated membrane protein 1 and 2 (LAMP1 and LAMP2), which are abundant also in lysosomes, of LBPA present mainly within internal membranes and of several acid hydrolases in the lumen. LEs have a pH between 6.0–4.8 and represent the sorting center from where the mannose-6-phosphate receptors (MPRs) are recycled to the *trans*-Golgi network (Gruenberg and Stenmark, 2004).

Lysosomal hydrolases are synthesized in the endoplasmic reticulum (ER) and are then transported to *cis*-Golgi network, where they are covalently modified by the addition of mannose-6-phosphate (M6P) groups and then transported in the *trans*-Golgi network (TGN) and delivered to the LEs (Coutinho *et al.*, 2012). Indeed, M6P-tagged proteins are recognized by MPRs in the TGN and then are sorted and delivered to the LEs by means of vesicles budding (Rouillé *et al.*, 2000; Coutinho *et al.*, 2012). There are two different MPRs: cation-dependent (CD) and cation-independent (CI). Even if they share similar sequences, these receptors are not synonymous components, but they bound different lysosomal enzymes (Ghosh *et al.*, 2003; Coutinho *et al.*, 2012).

Defects in targeting lysosomal enzymes cause mucopolisaccharidosis II (Olkonen and Ikonen, 2006).

Vesicles that work as intermediate carriers in this pathway are coated by a mechanism that involves adapter protein (AP) complexes, Golgi localized γ -ear-containing ARF-binding proteins (GGAs) and clathrin. While AP-1 mediates transport of MPR-bounded proteins from Golgi to LEs, transmembrane proteins that have to be delivered to LEs, including the glycoproteins LAMP-1 and LAMP-2, are sorted by AP-3 by recognition of tyrosine-based or dileucine based sorting signals. These proteins are then transported to LEs in vesicles that are different from those containing MPR-bounded proteins (Karlsson and Carlsson, 1998; Rouillé *et al.*, 2000). When vesicles containing MPR-bound proteins reach the LEs, the lower pH in the LEs causes the detachment of MPR; in this way hydrolases remain in the LEs and are then transported to lysosomes, while MPRs are recycled to the TGN by means of Rab9-TIP47 and a complex known as retromer. Other membrane proteins are not recycled but, instead, are routed to lysosomes (Rouillé *et al.*, 2000; Coutinho *et al.*, 2012). Even though acidic hydrolases coming from TGN seem to be mainly delivered to LEs, these proteins also arrive to EEs contributing to their maturation (Huotari and Helenius, 2011; Bonifacino and Rojas, 2006). Indeed, both EEs and LEs communicate with TGN in a bidirectional way, with acidic hydrolase receptors, transmembrane enzymes and SNAREs cycling between these compartments (Huotari and Helenius, 2011; Bonifacino and Rojas, 2006).

Maturation of endosomes requires changes in several regulatory proteins (Huotari and Helenius, 2011; Solinger and Spang, 2013). An important event is the so-called Rab5/Rab7 switch where Rab5, mostly expressed in EEs, is replaced by

Figure 3 Differences between EEs and LEs. LEs are characterized by a more acidic environment compared with EEs. The acidic pH is assured by V-ATPase, which, hydrolyzing ATP, introduces protons in the LE lumen. The correct function of V-ATPase is allowed by maintenance of charge flow mediated by ion channels, which promote anion influx and cation efflux, and by Na^+/K^+ ATPase. These processes start in EEs (gray arrows), where pH range is comprised between 6.8 and 6.1, but are more intense in LEs (black arrows) whose pH is comprised in a range between 6.0 and 4.8. Early endosomal Rab proteins, membrane proteins and lipids, tethering and fusion machineries are replaced by late endosomal ones. Furthermore LEs are characterized by the inclusion of several acid hydrolases and transmembrane glycoproteins incoming from TGN. For clarity of representation in this figure ILVs are not included.

Rab7, mostly expressed in LEs (Figure 3). Also, PI(3)P abundant in early endosomal membranes is substituted by the PI(3,5)P2 and the class C core vacuole/endosome tethering factor (CORVET) is replaced by late endosomal/lysosomal homotypic fusion and vacuole protein sorting (HOPS) complex (Figure 3). In addition, early endosomal SNAREs (soluble NSF (N-ethylmaleimide (NEM)-sensitive factor) attachment protein receptors) important for fusion are substituted by late endosomal SNAREs (Figure 3).

Role of pH and Ion Concentrations in Endosomal Maturation

pH plays an essential role in the maturation of endosomes and in their fusion with lysosome. Acidification of endosomes is required for the release of lysosomal hydrolases incoming from TGN, for the genesis of ILVs, and for sorting and budding

of endosomal carrier vesicles that move from early to late endosomes (Cipriano *et al.*, 2008; Scott and Gruenberg, 2011). Furthermore acidic environment in lysosomes allows the activation of degradative enzymes and the transport of ions and small molecules across the lysosomal membrane (Cipriano *et al.*, 2008). pH in these organelles becomes progressively lower and this gradient plays an important role in the correct delivery of molecules. The progressive acidification of endosomes (starting from a 6.8–6.1 range in EEs and culminating in 6.0–4.8 range in LEs and about 4.5 in lysosomes), that drives molecules through the pathway, is assured by vacuolar (H^+) ATPases (V-ATPases) (Cipriano *et al.*, 2008). Alterations of pH in LEs and lysosomes have been detected in cancer cells (Cipriano *et al.*, 2008).

V-ATPases are composed of a cytoplasmic sector (V_1), that contains eight different subunits (A-H) and is involved in the binding and hydrolysis of ATP, and a membrane-integral sector (V_0), that contains six different subunits (a, c, c', c'', d, and e)

and regulates the proton transport into the lumen of endomembrane organelles (Cipriano *et al.*, 2008). These proton pumps are characterized by a rotary mechanism that starts in the V₁ domain after the hydrolysis of ATP and involves the D, F, and d subunits and the proteolipid ring (composed of c', c' and c'' subunits); when the proteolipid ring rotates, proton is transferred from the cytoplasm to the lumen, contributing to the acidification of the environment (Cipriano *et al.*, 2008).

Even though acidification is essential for organelle function, ion concentration is also important for maturation of endosomes (Figure 3). In the absence of a regulation of ion flux in the endosome, V-ATPase would activate a self-inhibiting mechanism because of the electrochemical gradient; ion channels (i.e., for Cl⁻ or other anion influx and Ca²⁺, Na⁺, K⁺ and other cation efflux), as well as Na⁺/K⁺ ATPase, existing in the endosomal membrane assure the correct maintenance of charge flow (Scott and Gruenberg, 2011; Huotari and Helenius, 2011). However, ion concentration itself can regulate endosomal maturation beyond acidification. Differences in ion concentrations have been detected in the transition from EE to LE and lysosome: Cl⁻, Ca²⁺, and K⁺ concentrations increase, while Na⁺ concentrations decrease (Scott and Gruenberg, 2011; Figure 3). In particular it is clear that Ca²⁺ release from endosomes and lysosomes is important for fission and fusion events occurring in the endolysosomal pathway; endosomes and lysosomes represent an important source of Ca²⁺ because of the high concentration of this cation in the lumen (~0.5 mM in lysosomes and between 0.003–2 mM in the endosome) (Shen *et al.*, 2011). Furthermore, an anion binding site was found in transferrin demonstrating that also Cl⁻ has an essential role: indeed, increasing concentrations of this anion, in addition to a low pH, play a role in the release of iron from transferrin in EEs (Byrne *et al.*, 2010).

Perinuclear Clustering of LE and Fusion Events

After maturation, LEs cluster in the perinuclear area, near the microtubule-organizing center (MTOC) and are subjected to homotypic (LE-LE) and heterotypic (LE-lysosome) fusion events (Luzio *et al.*, 2007; Huotari and Helenius, 2011).

There are three alternative hypotheses about the mixing between the endosome and lysosome content. The first one proposes a vesicular traffic between the two organelles; the second one, called “kiss and run”, considers that endosomes and lysosomes continuously undergo fusion and fission processes. The third hypothesis can be considered an extension of “kiss and run” and assumes that direct fusion between late endosomes and lysosomes occurs to form an hybrid organelle, called endolysosome, in which degradation takes place; after this fusion, lysosomes are re-formed from endolysosome and become storage organelle for lysosomal hydrolases and membrane components that can be reutilized (Storrie and Desjardins, 1996; Luzio *et al.*, 2000; Huotari and Helenius, 2011). The latter two hypotheses are the more validated and can coexist (Bright *et al.*, 2005).

Similar to other fusion events, fusion process is composed mainly of three steps: tethering, formation of *trans*-SNARE complex, that acts as a bridge between the two organelles, and,

finally, membrane fusion (Luzio *et al.*, 2007). Thus, LEs in order to fuse with each other, with lysosomes and probably with other organelles containing material destined for degradation, depend on NSF, SNAPs (soluble NSF-attachment proteins), SNAREs, tethering factors and Rabs (Huotari and Helenius, 2011).

Tethering is an essential event for fusion as it allows organelles to form links between each other (Luzio *et al.*, 2007). In particular, CORVET is a Rab5 effector required for fusion between Rab5 positive endosomes, while HOPS is involved in tethering at late-endocytic stages and acts as Rab7 effector after the Rab7/Rab5 switch (Bröcker *et al.*, 2010; Balderhaar and Ungermann, 2013). Indeed overexpression of Rab7, Vps18p, and Vam6p (which are HOPS components) causes clustering of late-endocytic structures, while dispersion of the organelles was observed after depletion of Vps18p (Bucci *et al.*, 2000; Caplan *et al.*, 2001; Poupon *et al.*, 2003). Tethering subunits of HOPS complex and Rab7 act together in order to recruit SNAREs and promote membrane fusion (Solinger and Spang, 2013). Thus SNAREs form a complex that is composed of three Q-SNAREs (Vamp7 for heterotypic and Vamp8 for homotypic fusion) on one membrane and one R-SNARE (Syntaxin-7 and -8) on the other membrane. After this stable four helix bundle complex is formed, the bilayer mixing reaction starts. Heterotypic fusion is not driven only by SNAREs, as also Rab effectors and Ca²⁺ released from endolysosomes are essential regulators (Luzio *et al.*, 2007; Shen *et al.*, 2011). After fusion the NSF ATPase and its cofactor SNAP cause the recycle of SNAREs (Balderhaar and Ungermann, 2013).

Role of Rab Proteins

Rab GTPases are key regulators of membrane traffic and thus play an essential role also in endosome to lysosome transport, being involved in several different steps of this pathway as described before. Rab5, in particular, regulates several steps in the EEs formation and maturation: it controls cargo selection in vesicles, generation of phosphatidylinositol-3-phosphate lipid on EEs, homotypic fusion, motility of EEs on actin and microtubules tracks and activates signaling pathways on EEs by recruiting its effectors. Instead, Rab4 and Rab11 promote recycling events (Jovic *et al.*, 2010). Rab7 is involved in cargo sorting at the level of EEs, but it plays its main role in late-endocytic stages being required for the maturation of EEs in LEs (the so-called Rab7/Rab5 switch) (Girard *et al.*, 2014). Rab7 also regulates transport from LEs to lysosomes and controls clustering and fusion of late-endocytic structures and lysosomes in the perinuclear region. In addition, several Rab7 effectors can regulate positively (RILP, component of the retromer and HOPS complexes, Rabring7) or negatively (Rubicon and PLEKHM1) maturation and late-endocytic events (Huotari and Helenius, 2011). Interestingly, Rab7, through its effector RILP, seems to regulate also the endosomal pH. Indeed, RILP controls assembly and function of the V-ATPase by interacting with the V1G1 subunit (De Luca *et al.*, 2014). In the transition step between EEs to LEs, Rab9, which plays an essential role in lysosome biogenesis and late endosome morphology, increases, while other Rabs, such as Rab4,

Rab11, and Rab22 are lost (Riederer *et al.*, 1994; Ganley *et al.*, 2004; Huotari and Helenius, 2011).

Role of Cytoskeletal Elements and of Molecular Motors

All cytoskeletal elements (microtubules, actin filaments and intermediate filaments) are involved in endosome to lysosome transport and myosin, kinesin and dynein motors cooperate to assure correct organelle's movements (Minin and Moldaver, 2008; Granger *et al.*, 2014). Table 1 provides a list of cytoskeletal elements and motors that acting with Rab proteins and other interactors, promote several functions in the endosomal-lysosomal transport.

During all maturation steps previously described, EEs and LEs move along microtubules, transported by molecular

motors (Figure 4). Kinesin motors mediate mainly transport from the minus to the plus-end of microtubules, while dynein promotes transport in the opposite direction (Hirokawa, 1998). Movement of EEs from the periphery to the MTOC is controlled by the dynein–dynactin complex, which can be recruited by the microtubule-binding protein CLIP-170 after docking of endosomes on microtubules (Valetti *et al.*, 1999). On the other hand transport of EEs in the opposite direction is regulated by a member of kinesin superfamily (KIF), KIF16B, in a process controlled by the Rab5 GTPase and by its effector the PI(3)P kinase VPS34 (Hoepfner *et al.*, 2005). On EEs Rab5 also acts by means of another effector: Huntingtin (Htt) associated protein (HAP40) that recruits Htt on EEs thus mediating the transport of these organelles. Moreover the Htt-HAP40-Rab5 complex mediates the switch from one type of filaments to another: indeed overexpression of HAP40, which limits recruitment of Htt on the membrane, causes the

Figure 4 Transport on microtubules. Transport of EEs and LEs from the minus to the plus-end of microtubules is mediated by kinesin, whereas these organelles move to the microtubule-organizing center (MTOC) by means of dynein acting with dynactin. The transport of LEs to the MTOC mediated by Rab7 and RILP is represented in more details.

detachment of EEs from microtubules and the preferential binding of actin filaments (Pal *et al.*, 2006). Htt facilitates also dynein-mediated trafficking of LEs and lysosomes and regulates their association with microtubules (Caviston *et al.*, 2011). Htt mutations, causing defects in the movement of vesicles or organelles along cytoskeletal elements in late-endocytic transport, cause Huntington’s disease (Olkkonen and Ikonen, 2006). Recent findings demonstrated that another Rab protein, Rab11, regulates EEs morphogenesis and motility, interacting with the motor protein KIF13A (Delevoeye *et al.*, 2014).

LEs move to the perinuclear area where fusion events take place; this movement is mainly regulated by dynein (Aniento *et al.*, 1993; Bananis *et al.*, 2004). Attachment of LEs through dynein–dynactin complex is mediated by the Rab7 GTPase,

that, in its active form, cooperates with RILP, which is abundantly recruited on LEs membranes (Cantalupo *et al.*, 2001; Jordens *et al.*, 2001). Upon activation, Rab7 also interacts with ORP1L (oxysterol-binding protein-related protein 1 L) and thus a tripartite complex is formed. ORP1L transfers RILP to β III spectrin and this event is required for the translocation of late endosomes to MTOC (Johansson *et al.*, 2007). As well as RILP, BLOC-3 assures optimal attachment of late-endocytic organelles on the microtubules-dependent motors (Falcón-Pérez *et al.*, 2005). Recent evidences demonstrated that also an opposite-directed movement of LEs exists: indeed, interaction of Rab7 with FYVE and coiled-coil domain containing protein (FYCO) 1 regulates transport of LEs to the periphery (plus-end directed motility), probably by means of kinesin motors (Pankiv *et al.*, 2010).

Movement of endocytic organelles is mediated not only by microtubules, but also by actin cytoskeleton with myosin motors playing an essential role (DePina and Langford, 1999). Also, sorting of EGFR in MVBs destined for lysosomes degradation is mediated by its binding on actin filaments. This interaction could prevent the incorporation of receptor in the recycling pathway or could drive it in specific membrane compartments of endosomes destined for ILVs formation (Stoorvogel *et al.*, 2004). Traffic of protein cargo in MVBs is also mediated by myosin I that probably modulates the morphology of these organelles by interacting with actin (Salas-Cortes *et al.*, 2005). In fact, it was demonstrated that in mammalian cells endosomes and lysosomes are associated to myosin Ia that probably can tether organelle membranes to actin filaments, thus mediating the endosome-lysosome trafficking (Raposo *et al.*, 1999). Indeed this motor protein, working on actin filaments, was found to regulate the movement of lysosomes in cooperation with microtubules; these movement are rapid and direct along microtubules, while sometimes are short and random on actin filaments (Matteoni and Kreis, 1987; Prekeris *et al.*, 1999; Cordonnier *et al.*, 2001). Other myosins are instead important for endocytic recycling. Myosin VI, acting with Lemur tyrosine kinase2 (LMTK2), controls cargo delivery from EE to the endocytic recycling compartment while myosin Va interacts with several Rab proteins involved in recycling and it is required for the maintenance of Rab11 and Rab14-positive endosomes in the periphery of the cell (Lindsay *et al.*, 2013; Chibalina *et al.*, 2007).

As well as other cytoskeleton members, intermediate filament (IF) proteins control the degradative endocytic pathway (Styers *et al.*, 2004). Peripherin, α -internexin and vimentin bind to AP-3 complex, which is involved in transport between endosomes and lysosomes or related compartments (Styers *et al.*, 2004). IFs provide positional information for AP-3 and late-endocytic organelles. Furthermore, IFs regulate the sorting function of AP-3. In fact, AP-3 mediated sorting of LAMP1 and LAMP2 is prevented in absence of vimentin (Styers *et al.*, 2004). In support of these data we found that Rab7 interacts with and regulates the assembly of peripherin and vimentin (Cogli *et al.*, 2013a,b). As Rab7 is involved in endosome to lysosome transport, peripherin and vimentin, acting with this small GTPase, could play an important role in positioning and transport of late-endocytic organelles.

Conclusions and Perspectives

- Endocytosed cargo is delivered to EEs, where material is sorted and destined for degradation in lysosomes or recycled.
- Maturation of EEs in LEs is a complex process, not yet fully understood, comprising several modifications of the organelle environment. These events include formation of ILVs, progressive acidification, change of ion concentrations, substitution of membrane and luminal molecules, and inclusion of lysosomal proteins incoming from TGN.
- LEs cluster in the perinuclear area and fuse with each other or with lysosomes. These fusion events probably occur by “kiss and run” mechanisms that involve several proteins such as NSF, SNAPs and SNAREs.

- Rab proteins and their effectors play a key role, regulating tethering, maturation, transport, and fusion steps of endocytic organelles.
- Cytoskeletal elements are fundamental for organelle movement, organelle transport to the perinuclear region, and organelle positioning, and are regulated by Rab proteins.

Although in the past 15 years a huge amount of data have been produced on the molecular mechanism underlying the late steps of endocytosis (for instance unraveling mechanisms of sorting and degradation of membrane receptors by the ESCRT machineries), more work is required in order to better understand transport and relationships between endosomes and lysosomes. Indeed, several aspects of this transport including biogenesis of MVBs, LEs and lysosomes, role of cytoskeletal elements and signal transductions pathways need to be further investigated.

Glossary

Avidity A phenomenon often seen during assembly of large macromolecular complexes, whereby numerous weak-binding affinities simultaneously produce a strong but transient interaction. Also termed coincidence detection or a dual key strategy.

Clathrin-coated vesicle A class of membrane-bounded intracellular transport carriers that are temporarily encased within a polyhedral clathrin protein lattice. The coat functions to both deform the membrane into a ~100 nm-sized vesicle and to select the cargo packaged into the vesicle.

Integrins A set of heterodimeric transmembrane cell surface receptors that link the extracellular matrix to the intracellular actin-based cytoskeleton.

Interaction hub A designation for a protein or assembled protein complex that is able to interact with numerous distinct partner proteins or lipids, either one at a time or simultaneously.

Selectin A group of Ca^{2+} -dependent, carbohydrate recognizing transmembrane adhesion, and signaling proteins.

Introduction

Cholesterol is a fundamentally important constituent of animal cell lipid bilayers. Being the only inflexible heterocyclic (sterol) lipid in the membrane matrix, the pathway for cholesterol biosynthesis is distinct from that of phospholipids and glycosphingolipids (Holthuis and Menon, 2014). Cellular production of the 27-carbon-containing cholesterol molecule begins with acetyl-Coenzyme A and depends on 26 sequential enzymatic steps. In complex organisms, although each cell type generally has the intrinsic capability to assemble cholesterol from an acetate precursor, supply of cholesterol through the diet is often preferable. In fact, when cholesterol levels become limiting in cells, an elegant molecular response is initiated that not only induces coordinated transcription and translation of the enzymatic suite necessary for cholesterol biosynthesis, but also drives parallel upregulation of the principal transmembrane receptor required for internalization of dietary-derived cholesterol (Goldstein and Brown, 2009). This permits cells to scavenge any available extracellular cholesterol source as effectively as possible; in fact, this is a clinically important aspect of therapeutic statin administration.

This article deals with the process of external cholesterol uptake at the cellular level. The operation depends upon clathrin-mediated endocytosis, an evolutionarily ancient mode of internalization of extracellular macromolecules and surface membrane constituents within small (~100 nm), short-lived, vesicular shuttles. Characterization of the mechanistic basis of the internalization and intracellular mobilization of plasma-borne cholesterol mapped the basic features of the endocytic pathway (Brown and Goldstein, 1979; Goldstein and Brown, 2009), and provided the basis for further structural and functional dissection of numerous endocytic trafficking events. The focus here is primarily on the human low density lipoprotein (LDL) receptor; over 1000 distinct mutations in the *LDLR* gene have been characterized in familial hypercholesterolemia patients (Fokkema *et al.*, 2005; Hobbs *et al.*, 1990) and interesting new details about LDL receptor

trafficking have come recently from three clinically related human disease states (Soutar and Naoumova, 2007; Sharpe *et al.*, 2014).

Low Density Lipoprotein Biosynthesis

While the LDL receptor is ubiquitously expressed, production of plasma LDL is linked directly to the normal operation of the liver in placental mammals. Initially, fatty acids, in the form of triacylglycerols, and exogenous esterified cholesterol, derived largely from dietary chylomicron remnants, are assembled into a monolayer-bounded lipoprotein particle within the lumen of the hepatocyte endoplasmic reticulum. The particle is lipidated around a core of a single apolipoprotein B100 (apoB100) molecule, a necessary and very large (>5000 kDa) transport protein (Rutledge *et al.*, 2010). The smaller exchangeable apolipoprotein E (apoE) protein (36 kDa) is also co-translationally translocated into the lumen of the hepatocyte endoplasmic reticulum. The incorporation of apoE into nascent apoB100-positive lipoprotein particles enhances biosynthesis and secretion. Upon exocytic release into the circulation, the macromolecular assemblage (30–50 nm in diameter) is designated very low density lipoprotein (VLDL). VLDL supplies peripheral tissues (primarily muscle) with fatty acids as an energy source, and allows adipocytes to stockpile lipid from the hydrophobic triacylglyceride/esterified cholesterol store within intracellular droplets. This continuous remodeling of circulating VLDL particles by capillary-bed lipoprotein lipases, with concomitant loss of associated apoE and the exchangeable lipoprotein lipase cofactor apoC-II (both salvaged by plasma high density lipoprotein (HDL)), alters the density of the particle, ultimately generating LDL that is relatively depleted of triglycerides but substantially enriched with cholesteryl esters within the hydrophobic core. The now ~20-nm-sized LDL particle contains apoB100 as the only protein cofactor and binds exclusively to the LDL receptor. The circulating macromolecular particle gains access to the cell

interior from body fluids through the LDL receptor on the plasma membrane physically engaging apoB100 with nanomolar affinity, followed rapidly by receptor-mediated endocytosis (Goldstein and Brown, 2009).

The LDL Receptor

Receptor Structure

The LDL receptor is a type I transmembrane glycoprotein (Brown and Goldstein, 1979; Goldstein and Brown, 2009;

Hobbs *et al.*, 1990; Soutar and Naoumova, 2007). Because of the clinical significance of this protein, it represents the founding member of a larger LDL receptor superfamily of proteins, characterized by a shared modular architecture (Table 1). By far the bulk of the mass of these receptors is located extracellularly, and the LDL receptor is composed of multiple, tandemly arrayed functional luminal modules. An extreme N-terminal signal peptide begins the immature polypeptide but is removed in the endoplasmic reticulum. The mature protein contains a set of seven serially arranged, nonidentical cysteine-rich, Ca^{2+} -coordinating the so-called LDL receptor type A (LA) or complement-type ligand-binding

Table 1 Human genes and proteins related to LDL receptor biology

Gene	Protein	Function	UniProt accession number
<i>LDLR</i>	Low density lipoprotein receptor	Internalization of LDL	P01130
<i>APOB</i>	Apolipoprotein B100	Lipoprotein cofactor	P04114
<i>APOE</i>	Apolipoprotein E	Lipoprotein cofactor	P02649
<i>VLDLR</i>	Very low density lipoprotein receptor	Internalization of VLDL, Reelin signaling	P98155
<i>LRP8/APOER2</i>	Low density lipoprotein receptor-related protein 8/apoE receptor 2	Reelin signaling	Q14114
<i>MESDC2</i>	LDLR chaperone MESD/boca	Endoplasmic reticulum molecular chaperone	Q14696
<i>LRPAP1</i>	α 2-macroglobulin receptor-associated protein	Endoplasmic reticulum molecular chaperone	P30533
<i>SELP</i>	P-selectin	Cell adhesion receptor	P16109
<i>AMN1</i>	Protein AMN1 homolog/amnionless	Molecular chaperone/scavenger receptor subunit	Q8IY45
<i>CLTC</i>	Clathrin heavy chain 1	Coat protein	Q00610
<i>CLTA</i>	Clathrin light chain A	Coat protein subunit	P09496
<i>CLTB</i>	Clathrin light chain B	Coat protein subunit	P09497
<i>AP2A1</i>	AP-2 complex α -1/ α_A subunit	Coat component/sorting adaptor	O95782
<i>AP2A2</i>	AP-2 complex α -2/ α_C subunit	Coat component/sorting adaptor	O94973
<i>AP2B1</i>	AP-2 complex β 2 subunit	Coat component/sorting adaptor	P63010
<i>AP2M1</i>	AP-2 complex μ 2 subunit	Coat component/sorting adaptor	Q96CW1
<i>AP2S1</i>	AP-2 complex σ 2 subunit	Coat component/sorting adaptor	P53680
<i>LDLRAP1/ARH</i>	Low density lipoprotein receptor adapter protein 1/autosomal recessive hypercholesterolemia protein	Clathrin-associated sorting protein/cargo specific adaptor	Q5SW96
<i>DAB2</i>	Disabled homolog 2	Clathrin-associated sorting protein/cargo specific adaptor	P98082
<i>DAB1</i>	Disabled homolog 1	Signal transduction adapter	O75553
<i>ITGB1</i>	Integrin β 1	Extracellular matrix receptor	P05556
<i>SNX17</i>	Sorting nexin 17	Cargo-selective adaptor	Q15036
<i>NPC1</i>	Niemann-Pick C1 protein	Cholesterol transport transmembrane protein	O15118
<i>NPC2</i>	Niemann-Pick disease type C2 protein/Epididymal secretory protein E1	Luminal cholesterol transport protein	P61916
<i>NR1H3</i>	Oxysterols receptor LXR- α /Liver X receptor α	Transcription factor	Q13133
<i>NR1H2</i>	Oxysterols receptor LXR- β /Liver X receptor β	Transcription factor	P55055
<i>UBC</i>	Polyubiquitin C/ubiquitin	Posttranslational degradation signaling molecule	P0CG48
<i>MYLIP/IDOL</i>	E3 ubiquitin-protein ligase MYLIP/Inducible degrader of the LDL receptor	E3 ubiquitin ligase	Q8WY64
<i>EPN1</i>	Epsin-1/EPS-15-interacting protein 1	Clathrin-associated sorting protein/cargo specific adaptor	Q9Y6I3
<i>UBE2D1</i>	Ubiquitin-conjugating enzyme E2 D1	E2 ubiquitin-conjugating enzyme	UBE2D1
<i>PCSK9</i>	Proprotein convertase subtilisin/kexin type 9	Receptor degradation regulator	Q8NBP7

repeats, three epidermal growth factor (EGF) precursor-homology repeats (designated EGF-A–EGF-C) with a so-called YWTD domain, which folds into a six-bladed β -propeller, interposed between the second and third EGF repeat, preceding a serine/threonine-enriched juxtamembrane O-linked oligosaccharide domain. This extracellular assemblage is followed by the transmembrane segment of 22 nonpolar amino acids and, finally, by a 50-residue cytosolic domain (Figure 1). The VLDL receptor and the apoE receptor 2 (apoER2) are structurally highly homologous to the LDL receptor. Other members of the superfamily, including the LDL receptor-related protein 1 (LRP1) and the giant renal scavenger receptor megalin (also designated LRP2), have homologous but distinct combinations of the luminal repeats (Figure 1). In the

majority of cases, the precise role of each of the domain units within these mosaic receptor assemblages is not definitively established. Certainly, not all of the repetitive units contact the ligand(s) simultaneously. Evolutionarily related and functionally comparable receptors are also found in chordates and invertebrates; in insects (Figure 1) they are involved in yolk accumulation in developing oocytes and in shuttling the invertebrate hemolymph lipoprotein-like particle termed lipophorin (Rodenburg and Van Der Horst, 2005).

The complex ectodomain architecture of these receptors requires at least two dedicated endoplasmic reticulum molecular chaperones. The Boca/mesoderm development (MESD) protein is necessary for the proper folding of the numerous β -strands that make up the toroidal β -propeller

Figure 1 The LDL receptor superfamily. Schematic depiction of the domain organization of the human (*Homo sapiens*) mature LDL receptor and structurally related family members from both chordates and invertebrates (*Drosophila melanogaster*). The various serially arranged domains in the protein models are not drawn to scale, and the N-terminal signal sequence of each receptor, removed by proteolysis within the endoplasmic reticulum, is not shown.

domain(s) (Culi *et al.*, 2004), while receptor-associated protein (RAP) is responsible for efficient export of receptors from the endoplasmic reticulum (Bu, 2001) and appears to prevent inappropriate ligand engagement during passage along the biosynthetic secretory pathway by acting as a pseudoligand. This is important because LDL and VLDL receptors, as well as LRP1, are constantly being produced in hepatocytes, where VLDL is also being synthesized simultaneously within the lumen of the endoplasmic reticulum.

LDL Receptor Mutants

As indicated above, inherited defects in the LDL receptor gene lead to familial hypercholesterolemia, an autosomal-dominant disease characterized by high circulating LDL-cholesterol levels, premature atherosclerosis and increased risk of coronary artery disease. The huge assortment of *LDLR* mutations makes the prevalence of familial hypercholesterolemia allele heterozygosity about 1:200 worldwide (Nordestgaard *et al.*, 2013). Disease-associated mutations occur scattered over all 18 exons of the *LDLR* gene on chromosome 19, with the highest mapped density within exon 4 that encodes ligand-binding repeats LA3-6 (Fokkema *et al.*, 2005). The cellular consequences of *LDLR* mutations fall into five phenotypic/functional groups, designated Class 1–5 (Hobbs *et al.*, 1990). These range from deletions and missense, nonsense or frameshift mutations that

produce aberrant proteins that never fold satisfactorily or exit the endoplasmic reticulum (Class 1), to receptor forms that traverse the biosynthetic pathway and are successfully inserted into the plasma membrane, but fail to bind the exogenous LDL ligand (Class 3). Thus the various inherited pathologic mutations define numerous sequential stages during the biosynthesis and cellular functioning of the LDL receptor (Figure 2), but clinically all lead to an operationally defective phenotype and ensuing hypercholesterolemia.

Endocytic-sorting signals

Some C-terminally truncated forms of the defective LDL receptor do reach the cell surface and properly bind LDL (Class 4), but stagnate on the plasma membrane due to a lack of the intracellular segment (Hobbs *et al.*, 1990; Soutar and Naoumova, 2007). Dissimilar to the wild-type LDL receptor (Anderson *et al.*, 1982), mutant allele-encoded receptors without a cytosolic portion fail to cluster at clathrin-coated regions on the plasma membrane. This finding revealed definitively that a cytosolically disposed positive molecular determinant is necessary for selective concentration and import of LDL receptors into the cell interior within clathrin-coated vesicles. Among the numerous characterized clinical *LDLR* mutations within the cytosolic domain, arguably the most illuminating was from patient J.D. (Davis *et al.*, 1986). This unfortunate compound-heterozygous individual inherited a

Figure 2 LDL receptor biosynthesis and trafficking itineraries as revealed by familial hypercholesterolemia mutations. A stylized cartoon of a mammalian cell, highlighting the major intracellular organelles involved in LDL receptor biosynthesis and endocytic trafficking. Organelles along the biosynthetic secretory pathway are bounded in white, while endocytic compartments have a black outline. The primary site affected by the different inherited familial hypercholesterolemia mutations in the *LDLR* gene are indicated. Class 1: null alleles with defective synthesis that never progress past the endoplasmic reticulum; Class 2: transport defective alleles that do not transit past the Golgi complex; Class 3: binding-defective alleles; Class 4: internalization-defective alleles that stagnate on the cell surface, and Class 5: recycling-deficient alleles (Hobbs *et al.*, 1990; Goldstein and Brown, 2009).

single point mutation from his father that resulted in a Y807C substitution in the mature LDL receptor. The maternally inherited *LDLR* allele was a Class 1 null (Brown and Goldstein, 1979). Just like receptors missing the cytosolic portion entirely, the tyrosine-to-cysteine mutation strands the liganded LDL receptor at the cell surface. Thus, a native aromatic tyrosine side chain at position 807 is a critical chemical requirement for LDL receptors to be able to cluster into specialized dimpled zones on the cell surface as a prelude to internalization (Davis *et al.*, 1986). Initially, the necessary signal seemed to be a tetrapeptide ⁸⁰⁴NPVY (Chen *et al.*, 1990), but detailed analysis deduced a more general consensus [YF]XNPX[YF], where '[]' indicate residues permissible at that position and 'X' denotes any amino acid.

The discovery of tyrosine-based internalization information within the primary sequence of an important transmembrane protein led to swift evaluation of numerous other well-studied transmembrane-spanning receptors. Gratifyingly, a vital tyrosine located within the cytosolic domain and positioned close to the membrane bilayer interface was found to govern the rapid uptake of several surface receptors. Perhaps the most widely recognized is the ²⁰YTRF sequence at the amino terminus of the transferrin receptor 1 (Jing *et al.*, 1990), a type II transmembrane protein, but the ²³⁵³YSKV in cation-independent mannose 6-phosphate receptor (Canfield *et al.*, 1991) and ²⁵⁵YRGV within the smaller cation-dependent mannose 6-phosphate receptor (Johnson *et al.*, 1990) cytosolic segments also led the way in defining the so-called YXXØ sorting signal, where 'Ø' designates a bulky hydrophobic residue (Traub, 2009).

The YXXØ signal is recognized directly by the heterotetrameric AP-2 clathrin adaptor complex. This makes intuitive sense as, after clathrin, AP-2 is the most abundant protein in purified clathrin-coated vesicles derived from the plasma membrane, and AP-2 is positioned between the cargo-containing membrane layer and the outer polymerized clathrin coat (Traub, 2009). Of the four co-assembled AP-2 chains (α , β 2, μ 2 and σ 2), it is the ~50-kDa μ 2 subunit that physically engages YXXØ signals (Ohno *et al.*, 1995). The X-ray crystal structure of a YQRF signal bound to μ 2 shows that the YXXØ signal forms what is termed a β -augmentation: the polypeptide signal forms a short antiparallel β -strand that hydrogen bonds temporarily to the edge of the β 16 strand of the immunoglobulin-like β -sandwich μ 2 C-terminal domain (Owen and Evans, 1998). In this binding configuration, the two anchor residues, the tyrosine and the hydrophobic 'Ø', each occupy spatially complementary, hydrophobic-lined pockets on the surface of μ 2 and, in the tyrosine-accepting pocket, Asp176 accepts a critical hydrogen bond from the signal tyrosine hydroxyl. This accounts for the tight chemical selectivity of this side chain in the YXXØ signal.

It was clear already at the outset, however, that there were fundamental biochemical distinctions between the FDNPVY signal delineated in the LDL receptor and the more common YXXØ signal. Mutation of the tyrosine ablates sorting to bulk-flow levels (about a 5- to 10-fold decrease) in altered YXXØ signals (Jadot *et al.*, 1992), even if the switch is to phenylalanine. Again, this is because the tyrosine hydroxyl is a critical hydrogen bond donor (Owen and Evans, 1998). Yet, in the LDL receptor, substitution of Tyr807 with phenylalanine

causes no meaningful alteration in trafficking, and a more bulky tryptophan side chain switch impedes internalization only modestly (Davis *et al.*, 1986, 1987). But other non-aromatic side chains cannot substitute in directing efficient LDL receptor internalization (Davis *et al.*, 1986, 1987). A chicken LDL receptor has an ⁸⁶⁵FGNPLF signal and operative [YF]XNPX[YF]-type signals in the *Homo sapiens* transmembrane proteins P-selectin (⁸²¹FTNAAF) and amnionless (⁴⁰⁶FRNPVF and ⁴⁴¹FVNPLF) also contain naturally occurring phenylalanine residues at the position corresponding to Tyr807 in the LDL receptor. The two chemically distinct 'tyrosine-based' signals also saturate distinct sorting machinery in cells; forced overexpression of the transferrin receptor competes with other YXXØ-displaying transmembrane cargo, but not with the LDL receptor, for internalization (Warren *et al.*, 1998). Yet, despite this information revealing a dichotomy between the two types of tyrosine-based internalization signals, there were reports of a general structural analogy between the FXNPXY and YXXØ signals (Collawn *et al.*, 1990) and even that, like YXXØ, the FXNPXY polypeptide bound physically to the AP-2 μ 2 subunit (Boll *et al.*, 2002).

Cargo-Selective Clathrin Adaptors for the LDL Receptor

Definitive identification of dedicated adaptors specific for the [FY]XNPX[YF] signal came from two different lines of investigation. In the first, the advent of facile RNA interference (RNAi) methodology allowed silencing the mRNA transcript (s) encoding the subunits of the heterotetrameric AP-2 complex. Somewhat unexpected at the time, because AP-2 μ 2 gene disruption in mice is lethal, this approach revealed that clathrin-mediated uptake of transferrin and LDL could be uncoupled (Motley *et al.*, 2003). Cells transfected with small interfering RNAs targeting the AP-2 μ 2- or α -subunit mRNA transcript still take up LDL (Keyel *et al.*, 2006; Motley *et al.*, 2003; Maurer and Cooper, 2006; Eden *et al.*, 2007), concordant with LDL receptor internalization not being affected by excess YXXØ-displaying cargo (Warren *et al.*, 1998). Internalization of transferrin, however, is strongly inhibited by μ 2 RNAi, as anticipated.

Disabled Homolog 2

A probable explanation for the continued internalization of LDL in AP-2 extinguished cells comes from the identification of Disabled-2 (Dab2) as a *bona fide* clathrin-coat component (Mishra *et al.*, 2002a; Morris and Cooper, 2001; Maurer and Cooper, 2006). Like AP-2, Dab2 is a steady-state component of clathrin-coated structures at the plasma membrane (Table 1). In fact, part of the reason why Dab2 is localized to endocytic clathrin zones is that the protein interacts physically with AP-2 (Morris and Cooper, 2001). Significantly, this interaction is not competitive with the YXXØ contacting site on μ 2 but, instead utilizes independently folded C-terminal appendage domains that project off the trunks of the large α and β 2 chains of AP-2 and operate as interaction hubs. Dab2 also engages clathrin directly, and the molecular information to bind the core clathrin coat proteins is displayed as a series of

Figure 3 Key endocytic-sorting machinery involved in LDL receptor transport and turnover. Schematic illustration of the overall domain organization of LDL receptor binding/sorting proteins. The extended intrinsically disordered regions of Dab2, ARH, and epsin-1 are indicated by the narrow black lines and house the SLiMs. SS; signal sequence, which is removed by signal peptidase during co-translational translocation of PCSK9 into the endoplasmic reticulum.

serially arrayed short linear motifs (SLiMs) (Mishra *et al.*, 2002a; Morris and Cooper, 2001). These are located within a long C-terminal region of Dab2 that is predicted to be intrinsically disordered (Figure 3).

The architecture of Dab2 also reveals an N-terminal phosphotyrosine-binding (PTB) domain. The PTB domain is a folded ~150 amino acid module structurally related to the phospholipid binding pleckstrin-homology (PH) domain. But the domain name is clearly a misnomer because early on it was plainly established that the requirement for an anchor phosphotyrosine residue was not absolute; instead, a consensus binding sequence [FY]XNPXY was evident. Disabled homolog 1 (Dab1) has a phylogenetically related PTB domain but the C-terminal portion of the protein is very divergent, although both are predicted to be intrinsically unstructured. Dab1 participates in the process of cortical lamination in the developing brain and operates on a genetic pathway with the VLDL receptor and ApoER2 and the large extracellular matrix protein ligand Reelin. Both Dab1 and Dab2 utilize the PTB domain to bind physically to LDL receptor superfamily [FY]XNPXY signals. From a structural perspective, the mode of engagement of the [FY]XNPXY peptide is quite unlike YXXØ signals binding to the $\mu 2$ C domain, although the β -augmentation is common to both (Figure 4). Still, taken together, the functional characteristics of Dab2 broadly parallel those of AP-2: Both are able to bind to clathrin and to each other, and interact with phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂), a regulatory phospholipid that is enriched within the cytosolic leaflet of the plasma membrane. While membrane docked, both AP-2 and Dab2 have customized folded modular domains that can recognize and engage characterized sorting signals (Figure 4). RNAi-mediated suppression of Dab2 mRNA produces the opposite phenotype to AP-2 RNAi; transferrin uptake is rapid but LDL receptors, despite being normal, accumulate in a diffuse pattern on the cell surface, analogous to internalization-defective hypercholesterolemia mutants (Mishra *et al.*, 2002a; Morris and Cooper, 2001; Keyel *et al.*, 2006).

The Autosomal Recessive Hypercholesterolemia Protein

The case for PTB domain adaptors regulating LDL receptor internalization was closed with the identification of the gene responsible for another human disease, autosomal recessive hypercholesterolemia (ARH). Patients affected by this disorder present with very similar clinical features to familial hypercholesterolemia individuals, but do not have mutations in the LDL receptor or AP-2 (Eden *et al.*, 2001; Norman *et al.*, 1999). The relevant distinguishing feature in these patients is the recessive pattern of inheritance (Khachadurian and Uthman, 1973). Mapping the defective gene locus in ARH patients to a site on the short arm of chromosome 1 (Eden *et al.*, 2001; Garcia *et al.*, 2001) revealed a cytosolic 308 amino acid protein with a PTB domain at the N-terminus (Garcia *et al.*, 2001; Figure 3). Within the greater PTB domain protein superfamily, the ARH and Dab1/2 PTB domains cluster as close phylogenetic relatives, separate from the domains found in phosphotyrosine signaling components (Traub, 2009). Atomic structures of numerous PTB domains bound to peptide ligands, including those from Dab2 and ARH, are available. Generally, the models reveal the molecular basis for selectivity of tyrosine over phosphotyrosine and vice versa, and why in some PTB domains a tyrosine or phenylalanine are interchangeable within the cognate [FY]XNPXY peptide signal. Moreover, the structures provide an explanation for non-competitive binding of the Dab2/ARH PTB domains to both PtdIns(4,5)P₂ and the [FY]XNPXY sequence (Figure 4).

The C-terminal stretch of the ARH protein (also designated LDL receptor-associated protein 1 (LDLRAP1)) is again predicted to be intrinsically disordered, but contains SLiMs that are responsible for binding to clathrin or AP-2 (Mishra *et al.*, 2002b; He *et al.*, 2002), functionally analogous to Dab2. Retroviral transduction of ARH cDNA into immortalized ARH patient lymphocytes restores LDL uptake in these cells (Eden *et al.*, 2002).

Because of the increased clathrin-coat connectivity dictated by multiple SLiMs in the larger Dab2 protein, Dab2-mediated uptake of the LDL receptor is independent of AP-2 and ARH (Maurer and Cooper, 2006). Nevertheless, at a fundamental cellular level, Dab2 and ARH are functionally redundant; cultured fibroblasts from ARH patients depend on Dab2 for efficient LDL internalization (Eden *et al.*, 2007; Keyel *et al.*, 2006). Why then are ARH patients hypercholesterolemic? The answer is that in humans, about 70% of circulating LDL is cleared through the liver (Soutar and Naoumova, 2007; Sharpe *et al.*, 2014; Goldstein and Brown, 2009). In fact, the liver is the major site of LDL receptor operation. However, hepatocytes do not express high levels of Dab2 (Keyel *et al.*, 2006), making LDL internalization exquisitely sensitive to the ARH protein concentration. The relative paucity of Dab2 in hepatocytes is supported by RNA sequencing data (Uhlen *et al.*, 2010). In adult liver, the LDL receptor mRNA expression level is about 10-fold higher than in kidney, while ARH transcript abundance is roughly equivalent. Dab2 mRNA expression is approximately 10 times lower in liver than in kidney. In adrenal gland, the original tissue from which the LDL receptor was purified biochemically, LDLR mRNA expression is roughly equal to that of liver, yet Dab2 transcript abundance is about eightfold higher in adrenals. Lymphocytes

Figure 4 The structural basis for cargo recognition along the endocytic pathway. (a and b) Combination ribbon and molecular surface representations of the Dab1 (a; PDB ID: 1NTV) and ARH (b; PTB ID: 3S06) PTB domains co-crystallized with either the apoE receptor 2 (NFDPVYRKT) or the LDL receptor (SINFDPVYQKTT) sorting signal, respectively. The bound signals are shown colored yellow in stick representation, with nitrogen atoms shaded blue and oxygen red. The location of the -5 to -1 residues relative to the FXNPXY anchor tyrosine, designated residue 0 (0 Y), is indicated, as are the N and C termini of each peptide. The key features of the β -augmentation-based interaction are the extended conformation of the -5 to -2 residues hydrogen bonded via the main chain to the underlying β -strand, the tight β -turn highly favored by the -2 position proline, which redirects the main chain of the peptide perpendicular to the axis of the β -strand it contacts. This orients the anchor tyrosine (or phenylalanine) to fit into a spatially complementary acceptor pocket (white broken oval). The cluster of basic side chains in the Dab1 PTB domain (Lys 45, Arg 76, His81, Lys82, Arg124, and Lys142) are shown in stick representation and the cohesive basic surface patch they generate that is utilized to bind to PtdIns(4,5) P_2 is indicated. Although this structure shown is from Dab1, the Dab2 PTB domain structure is nearly identical (but of lower resolution; PTB ID: 1M7E) and has analogous molecular surfaces that bind to [YF]XNPX[YF] signals and PtdIns(4,5) P_2 . (c) Ribbon/surface representation of the SNX17 FERM domain illustrating the close structural relationship between the FERM F3 subdomain and the PTB domain, and the conserved mode of peptide interaction. The tyrosine-based GTYGVFTNAAYDPTP signal from P-selectin is shown in yellow stick representation and colored as in A and B. Note that the mode of engagement with the F3 fold is highly similar to the PTB domain. Although this peptide does not contain a -2 position proline residue, a different NPXY peptide similarly crystallized with the SNX17 FERM domain (PTB ID: 4TKN) verifies the orientation of the -2 proline relative to the standard PTB domain.

similarly express low levels of Dab2 and depend on ARH for LDL receptor internalization (Eden *et al.*, 2002). Why co-expression of the functionally redundant Dab2 has been

selected against in these tissues is not entirely clear at present. An obvious possibility is that ARH expression primarily allows regulatory inputs that would not be possible with the

combined presence of both Dab2 and ARH. Importantly, while Dab2 is a steady-state building block of surface clathrin-coated structures, ARH deposition at these zones is strongly affected by cargo (LDL receptor) availability (Mettlen *et al.*, 2010). In addition, the α -helical SLiM within ARH that permits AP-2 engagement contacts the appendage domain of the β 2 subunit (Mishra *et al.*, 2002b; He *et al.*, 2002). A critical residue upon the AP-2 β 2 appendage required for this interaction is Tyr888, which is positioned in the central region of the contact interface. This residue undergoes tyrosine phosphorylation, with the size and charge of the reversibly attached phosphate reshaping the interaction surface and sterically preventing ARH binding (Chakraborty *et al.*, 2014). The high incidence of the pTyr888 modification in lymphocytes may explain why LDL receptors do not congregate in clathrin-coated structures at the surface of these cells at steady state, unlike fibroblasts (Eden *et al.*, 2002) and other cell types.

The LDL receptor thus displays a structurally distinct type of internalization signal that meshes with modular PTB domain adaptors as opposed to the standard AP-2 sorting adaptor. Dab2 and ARH are typical examples of clathrin-associated sorting proteins (CLASPs), an expansive set of cargo-selective proteins that diversify the sorting possibilities of clathrin-coated structures on the cell surface beyond the cargo recognition capabilities of AP-2 (Traub, 2009). Being encoded by the primary structure of the LDL receptor, the [FY]XNPX[YF] signal directs constitutive internalization irrespective of whether the receptor is ligand bound or not. For ARH, the privileged interaction surface on the AP-2 β 2 appendage permits noncompetitive LDL receptor uptake under conditions of extensive internalization of other cargo within a single vesicle.

Endosomal Dynamics

Concomitant with cargo capture, the transition from a gently curved clathrin-coated patch to a deeply invaginated clathrin-coated bud occurs within only a minute or two at 37 °C. After pinching off from the plasma membrane in a GTP-requiring step, clathrin-coated vesicles are rapidly uncoated in an ATP-dependent fashion. The released coat protomers reenter the cytosolic pool to initiate new rounds of coat assembly. The uncoated vesicles, laden with LDL and other cargo, very rapidly fuse with one another to generate a so-called early endosome compartment, initially positioned in the cortical region of the cell. Proteolytic degradation products of internalized apoB100 become detectable at about 30 min post uptake, meaning that the LDL particle has reached the lysosome within this time interval, and is being catabolized to constituent amino acids (Brown and Goldstein, 1979; Goldstein and Brown, 2009). Lysosomal cathepsin D is the principal degradative protease (Muller *et al.*, 2012). On the same time scale, lysosomal acid lipase removes the long-chain fatty acid esterified to cholesterol in the lipoprotein particle core. Incorporation of the dietary-derived cholesterol into cellular membranes then depends on a pair of disease-related cholesterol-binding proteins, Niemann-Pick type C1 (NPC1) and NPC2, which are located in the late

endosome/lysosome compartment at steady state (Goldstein and Brown, 2009).

The biological half-life of the LDL receptor is, by comparison, in excess of 15 h (Brown and Goldstein, 1979; Goldstein and Brown, 2009). In the presence of cycloheximide to prevent new protein synthesis, rapid LDL particle uptake and breakdown persists for several hours. This large difference between the lifetimes of the receptor and its ligand dictates that each LDL receptor typically participates in many rounds of reinsertion into the plasma membrane, internalization and recycling, before undergoing degradation itself. It is estimated that the round trip is completed by an LDL receptor every 10 min-or-so (Brown *et al.*, 1997; Goldstein and Brown, 2009). A necessary physical requirement for this to occur is the detachment and separation of the LDL and LDL receptor within the early endosomal compartment.

Uncoupling of LDL from the Receptor in Endosomes

The moniker 'ligand-binding repeat' explicitly connotes the fact that these elements represent the principal part of the extracellular domain of the LDL receptor that engages lipoproteins. Over 40% of *LDLR* sequence variations map to exons 2–6, which encode the LA repeat array (Hobbs *et al.*, 1990; Soutar and Naoumova, 2007; Fokkema *et al.*, 2005). These are primarily Class 3 – binding defective – alleles. Deletion and truncation studies show that for LDL, apoB100 binds to a segment containing LA repeats 3–7. The LDL receptor can also interact with apoE (on VLDL), and this requires the LA5 repeat (Rudenko and Deisenhofer, 2003; Andersen and Moestrup, 2014). A natively folded LA5 repeat is therefore necessary for any lipoprotein to bind productively to the LDL receptor. At least one biologically important role for the set of flexible, tandemly arrayed LA repeats in the LDL receptor is to increase ligand affinity through avidity phenomena, making the critical process of ligand uncoupling within the endosome feasible (Andersen and Moestrup, 2014).

The lineup of compact LA repeats coordinate Ca^{2+} with measured equilibrium dissociation constants (K_D s) in the nanomolar to low micromolar range, depending on the individual repeat (Rudenko and Deisenhofer, 2003; Andersen and Moestrup, 2014). Three intermolecular disulfide bonds form within each ~ 40 -residue LA repeat that underpin the structural integrity of the Ca^{2+} -coordinating acidic surface, the so-called Ca^{2+} cage (Brown *et al.*, 1997). Indeed, the overall cohesion and ligand-binding capability of these repeats can be disrupted either by disulfide bond reduction or by Ca^{2+} chelation. Also, Class 3 disease-producing mutations affecting cysteine or other cage residues similarly diminish LDL binding because the protein becomes nonfunctional (Brown *et al.*, 1997; Hobbs *et al.*, 1990; Soutar and Naoumova, 2007). Thus, Ca^{2+} obviously participates in high affinity ligand binding at the neutral pH of the extracellular milieu, but whether Ca^{2+} physically dissociates from the LA repeats in a mildly acidic endosomal environment, generated through the action of the transmembrane proton pump, the vacuolar ATPase, as a dedicated mechanism for localized unfolding/destabilization to release bound LDL, is not yet entirely clear. An LDL receptor with an intact set of LA repeats but with the abutting C-terminal region, which displays homology

with the membrane-attached EGF precursor (the EGF homology module), deleted entirely still binds to and internalizes LDL (Hobbs *et al.*, 1990; Rudenko and Deisenhofer, 2003). Yet there is no separation within the early endosome compartment. This finding puts important mechanistic constraints on the idea that a binary Ca^{2+} -coordination toggle switch represents an unusual form of Ca^{2+} intracellular signaling governing LDL release (Andersen and Moestrup, 2014).

The Class 5 familial hypercholesterolemia mutations in the *LDLR* result in failure of the receptor–ligand complex to properly dissociate within endosomes (Brown and Goldstein, 1979; Goldstein and Brown, 2009; Figure 2). These inherited defects map primarily to the EGF homology module encoded by exons 7–14 of the *LDLR*, pinpointing these integrated folded domains as important regulators of apoB100 attachment. Coordinated Ca^{2+} also stabilizes the fold of the 40–50 amino acid EGF-A and EGF-B (but not EGF-C) repeats in the LDL receptor; Ca^{2+} is bound with low micromolar affinity (Rudenko and Deisenhofer, 2003; Andersen and Moestrup, 2014). Because it is firmly established that Ca^{2+} efflux accompanies proton entry during early endosome maturation, Ca^{2+} regulation could be operative at the EGF homology module as well (Andersen and Moestrup, 2014). The crystal structure of the almost complete luminal portion of the LDL receptor at acidic pH (5.3) reveals why ligand rebinding is prevented in the endosome (Rudenko *et al.*, 2002). The chief result is that the LA4 and LA5 repeats form direct intramolecular contacts with the β -propeller in the EGF homology module, folding the extended LA repeat series over the EGF homology module and, thereby, occluding the major ligand-binding region of the receptor. Correctly positioned lysine residues in the β -propeller interact electrostatically with the Ca^{2+} cage regions of LA4 and LA5, presumably mimicking, intramolecularly, the binding of apoB or RAP (Rudenko and Deisenhofer, 2003; Andersen and Moestrup, 2014). Clearly, in this structure, the Ca^{2+} ions remain coordinated by the ligand-binding repeats.

So what then drives these intramolecular contacts to occur particularly at the lower pH of the endosome? Protonation of luminal histidine side chains is implicated in pH-responsive ligand release by other endocytic receptors. There are three interfacial histidine residues in the LA4/LA5- β -propeller interaction surface that may confer pH sensitivity (Rudenko and Deisenhofer, 2003). Provocatively, two of these residues are represented among *LDLR* mutant alleles (H190Y on LA5 and H562Y on the β -propeller) (Huang *et al.*, 2010; Rudenko and Deisenhofer, 2003). In a current model to explain LDL discharge in the endosome compartment (Huang *et al.*, 2010), LDL particle binding to the receptor involves the LA repeat tract, as well as the β -propeller surface containing His562 and His586. The protonation of these histidine residues that accompanies endosomal acidification reverses contacts with LDL and favors rapid intramolecular closure of the receptor ligand-binding interface (Huang *et al.*, 2010). It seems clear that a combination of Ca^{2+} , pH and domain configuration changes combine to promote optimal release of LDL (and VLDL) from the LDL receptor (Andersen and Moestrup, 2014). Future studies will no doubt clarify the precise biological role of each of these processes.

Selection of the LDL Receptor for Recycling to the Cell Surface

Once the LDL particle is no longer able to bind tightly to the LDL receptor within the acidified endosome lumen, geometric considerations play a significant role in directing the differential movement of the two separated binding partners. Narrow tubules begin to form on early endosomes, which emanate from the central spherical vesicular portion (Bonifacino and Rojas, 2006). The high surface-to-volume ratio of the emerging tubules biases them toward an enriched load of transmembrane receptors while restricting bulk ingress of bulky luminal macromolecules, especially large assemblages like LDL (Figure 2). Failure of the stoichiometric LDL–LDL receptor complex to separate causes the entire macromolecular complex to travel to the lysosome and get degraded. The maturing tubulovesicular endosome is an important sorting station and several compositionally distinct tubules are produced to convey cargo to different intracellular acceptor compartments as well (Bonifacino and Rojas, 2006). The mechanistic implication of this intrinsic sorting complexity within a morphologically plastic endosomal compartment is that the LDL receptor must be sequestered into the correct inchoate tubules to facilitate rapid and efficient recycling back to the plasma membrane.

Current evidence indicates that a member of the sorting nexin family, sorting nexin 17 (SNX17), is important to actively segregate the LDL receptor into the proper recycling tubules during the process of early endosome maturation (Table 1). The sorting nexins are soluble proteins generally deposited on endosomes at steady state, but what sets SNX17 apart from many other members of the sorting nexin family is the presence of a band 4.1/ezrin/radixin/moesin (FERM) domain (Teasdale and Collins, 2012; Figure 3). The FERM domain is a roughly 300 amino acid, trefoil-like shaped globular domain. The founding members of the FERM domain family are peripheral membrane proteins that utilize the domain as a lipid-binding linker between the extracellular matrix/plasma membrane and the assembled cortical cytoskeleton (Chishti *et al.*, 1998). Specifically, integrins can engage the FERM domain to connect extracellular cues to actin microfilaments. The part of the β -integrin chain that engages the FERM domain displays an FXNPXY signal, a sequence tract originally noted to be related to the LDL receptor (Chen *et al.*, 1990).

SNX17 is implicated in endosomal sorting of numerous LDL receptor superfamily members, including the LDL, VLDL and apoER2 receptors and LRP1 (Stockinger *et al.*, 2002; Burden *et al.*, 2004), as well as the structurally unrelated P-selectin (Williams *et al.*, 2004), amyloid precursor protein and certain β -integrins (Lee *et al.*, 2008; Steinberg *et al.*, 2012). These proteins are all unified by sharing [FY]XNPX[YF]-type sorting signals located within the cytosolic domain (Chen *et al.*, 1990). For the LDL receptor, experimental manipulation of the cytosolic SNX17 concentration or structure directly affects rates of receptor recycling and intracellular positioning. Essentially, loss of SNX17 shortens the biologic half-life and therefore the number of duty cycles each LDL receptor can perform; normally SNX17 prevents the LDL (and other recognized) receptors from traveling to the lysosome.

FERM domains are typically composed of three interlinked folded lobes, called F1, F2, and F3 (Figure 3), with the F3 lobe

structurally related to the aforementioned PTB domain. Atomic-resolution data on the SNX17 FERM domain explains how the [YF]XNPX[YF] signal is recognized, which is remarkably similar to how Dab1/2 and ARH bind to the same sequence (Figure 4). The closest paralogue, SNX31, and possibly the more divergent SNX27, may act in a functionally redundant fashion with SNX17; SNX27 associates directly with the P-selectin FTNAAAY signal (Ghai *et al.*, 2013; Traub, 2009).

An overlapping tract of the LDL receptor cytosolic domain therefore directs both internalization and recycling, but by being decoded by different molecular machinery. Yet, if PTB and FERM domains both engage the [YF]XNPX[YF]-type signal, why do they not operate promiscuously? The answer is that Dab2/ARH and SNX17 are directed to separate membrane surfaces by physically engaging differentially phosphorylated variants of phosphatidylinositol; PtdIns(4,5) P_2 at the plasma membrane and phosphatidylinositol 3-phosphate (PtdIns3P) in the endosomal compartment. Recognition of PtdIns3P by SNX17 is specified by the N-terminal ~110-residue phox-homology (PX) domain (Teasdale and Collins, 2012; Figure 3). The typical affinity of the PTB or FERM domain for the [FY]XNPX[YF] signal, or of the PX domain for PtdIns3P, is in the low micromolar range. This range of K_D s display interaction half times that persist for seconds to minutes (Hammond *et al.*, 2009). If sorting depended solely on these bimolecular interactions, it would be highly susceptible to promiscuous binding mistakes (error prone). One mechanism to diminish this deleterious possibility is to temporally integrate several low affinity contacts to guard against biological noise, in the form of nonspecific engagements by related (or unrelated) proteins. The proper associations are thus strengthened and prolonged at the correct compartmental membrane surface by the phenomenon of avidity; synchronous contacts with other proteins and lipids that facilitate appropriate macromolecular assembly formation and sorting. Because avidity is related to valency, the capability of the LDL receptor to form functional dimers will also assist in the fidelity of sorting.

Other SNX family proteins that direct sorting operations at the early endosome cooperate with scaffolding and cytoskeletal proteins, to which they bind physically (Teasdale and Collins, 2012). The precise mechanism by which SNX17 partitions the LDL for efficient recycling to the cell surface is not fully revealed. It is also yet to be resolved whether a single lengthy endosomal tubule contains multiple SNX17-, SNX1/2+retromer- and EHD-positive zones that can fragment to produce differentially trafficked cargo carriers destined for distinct downstream acceptor compartments.

Dynamic Modulation of LDL Receptor Surface Levels

Cholesterol Overload Responses

The impressive strategies that have evolved in animal cells to assure ample cholesterol supply are counterpointed by recently uncovered, yet equally striking, pathways to limit cholesterol over-accumulation at the cellular level. Cholesterol in excess of cellular demand undergoes oxidative modification. Accumulating oxidized forms of the sterol relay biological homeostatic information by binding to the nuclear receptor

family factors liver X receptor α (LXR α) and LXR β (Zelcer *et al.*, 2009; Hong and Tontonoz, 2014). Oxysterol-stimulated derepression of the LXR transcription factors promptly turns on a battery of genes that manage cholesterol efflux from the cell, the so-called reverse cholesterol transport (Sharpe *et al.*, 2014; Sorrentino and Zelcer, 2012; Zelcer *et al.*, 2009). Overall, the process is aimed at relocating excess cholesterol from within peripheral tissues back to the liver within HDL particles, and then excreting the returned cholesterol as bile salts. Under these conditions, the cellular abundance of the LDL receptor decreases. One intriguing target of LXRs is a 445 amino acid protein (Zelcer *et al.*, 2009) originally dubbed MYLIP (myosin regulatory light chain interacting protein) (Table 1). The domain organization of this protein illustrates that it is essentially composed of two modular parts: an N-terminal FERM domain and a C-terminal really interesting new gene (RING) domain (Figure 3), which immediately suggests a possible mechanism for the observed down-regulation of the LDL receptor. Together with the RING domain, which imparts E3 ubiquitin ligase capability, this particular LXR target gene could first identify and then post-translationally modify the LDL receptor with ubiquitin chains (constructed by covalent linkage of the 76 amino acid protein ubiquitin) to reroute the protein for lysosome delivery and catabolism. This is indeed the case, prompting the redesignation of MYLIP as an inducible degrader of the LDL receptor (IDOL) (Zelcer *et al.*, 2009). Neither the FERM nor RING domain alone diminishes LDL receptor abundance in cells; the protein must be intact to function in this way (Sorrentino *et al.*, 2011; Scotti *et al.*, 2013). Further, an LDL receptor lacking the intracellular domain is impervious to IDOL-mediated action; the cytosolic domain is necessary both for recognition by the IDOL FERM/RING domains and to provide an acceptor lysine (or cysteine) residue for ubiquitin addition (Sorrentino and Zelcer, 2012).

Despite IDOL and SNX17 both containing FERM domains, there is little primary sequence identity between the two proteins. Unfortunately there is no direct atomic-resolution structural information currently available for the IDOL FERM domain, but sequence comparisons reveal that it has an insertion within the F3 lobe that is unusual (Calkin *et al.*, 2011). Notably, LRP1 is not an IDOL substrate, so the FERM domain in this E3 ligase cannot recognize the [FY]XNPX[YF] signal in an identical manner to SNX17. Also, the principal acceptor lysine residue in the LDL receptor (Lys809), to which the initial ubiquitin is attached via an isopeptide linkage, is separated from the anchor Tyr807 (the position 0 Y altered in the J.D. point mutation) by only a single amino acid (Zelcer *et al.*, 2009). Residues N-terminal to the [FY]XNPX[YF] sorting signal appear crucial for IDOL-mediated ubiquitin addition to the LDL receptor at position Lys809; a consensus sequence of WXXKNXXS[IM]XF[DE] (where the trailing 'F' is the -5 position F of the [FY]XNPX[YF] sequence) is needed to bind to the IDOL FERM domain (Sorrentino *et al.*, 2013a; Calkin *et al.*, 2011). This reliance on a preceding amino acid tract to provide specificity-determining side chains for FERM engagement is analogous to how the TALIN FERM domain binds to β -integrins (Wegener *et al.*, 2007), and likely explains why IDOL evolved to contain a FERM and not a PTB domain to engage LDL receptor family targets (Calkin *et al.*, 2011). The IDOL

FERM has undergone functional selection to, first, facilitate recognition of only a subset of the LDL receptor superfamily proteins and, second, permit docking of the sorting signal in such a way that the ϵ -amino group of the Lys809 side chain is accessible for ubiquitin ligation (Sorrentino *et al.*, 2013a; Calkin *et al.*, 2011).

Strikingly, population gene sequencing efforts show that a possible gain-of-function (N342S) and a loss-of-function (R266X) IDOL variant are associated, respectively, with high and low circulating LDL-cholesterol levels in humans (Sorrentino and Zelcer, 2012). This ubiquitin-dependent mechanism to turn over the LDL receptor therefore impacts systemic LDL clearance in animals. The ubiquitination of the LDL receptor by IDOL dimers, working in conjunction with the E2 ubiquitin-conjugating enzymes UBE2D (Zhang *et al.*, 2011) or UBE2N (Sorrentino *et al.*, 2011), generates Lys63-linked polyubiquitin chains at the cell surface (Sorrentino *et al.*, 2011; Scotti *et al.*, 2013). IDOL also ubiquitinates the phylogenetically closest LDL receptor relatives, the VLDL and apoER2 receptors (Sorrentino and Zelcer, 2012). Similarly positioned lysine acceptor residues are found flanking the FXNPXY signals in these receptors. The isopeptide-linked bulky ubiquitin adduct most likely obstructs normal recognition of the FXNPXY signal by the PTB domain and instead directs the receptor for lysosomal degradation. Preliminary results suggest that the IDOL-directed route of intracellular movement to the lysosome is distinct from the normal trafficking itinerary of LDL-LDL receptor complexes (Figure 2), and does not require clathrin-mediated endocytosis (Sharpe *et al.*, 2014; Sorrentino *et al.*, 2013b). Rather, decoding of the ubiquitin signal is attributed to epsin, a 576 amino acid CLASP architecturally reminiscent of, and functionally analogous to, Dab2 and ARH (Figure 3), and (curiously) also a steady-state constituent of cell surface clathrin-coated structures (Traub, 2009). Instead of a PTB domain, epsin contains an epsin N-terminal homology (ENTH) domain, which binds to PtdIns(4,5) P_2 , and SLiMS within the intrinsically unstructured C-terminal region that interact with AP-2 and clathrin directly. Trailing after the ENTH domain are a set α -helical of ubiquitin-interacting motifs (Figure 3) that recognize Lys63-linked polyubiquitin chains (Traub, 2009; Piper *et al.*, 2014). New careful analysis shows that almost all (>95%) of internalization events from the plasma membrane are clathrin dependent (Bitsikas *et al.*, 2014), making the assertion that IDOL drives a different process (Scotti *et al.*, 2013; Sorrentino *et al.*, 2013b) somewhat provisional and requiring systematic reevaluation. Why a separate sorting route is necessary is not immediately obvious, as many signaling and nutrient receptors are effectively targeted for lysosomal degradation from the cell surface by the standard endosomal pathway utilizing Lys63-linked polyubiquitin as the sorting signal (Piper *et al.*, 2014).

The discovery of IDOL deftly highlights that appended ubiquitin can potentially override the normal trafficking behavior of the LDL receptor. What this means operationally is that when the LDL receptor arrives in the endosomal compartment, the default recycling itinerary governed by the FDNPVY signal is thwarted by the nearby, posttranslationally added ubiquitin chain. How does this happen? It turns out that Lys63-linked conjugation is actually a general way to

direct selected transmembrane cargo to the lysosomal compartment (Piper *et al.*, 2014). It is vital to recognize that this ubiquitin-dependent degradation of cell surface transmembrane proteins/cargo within the endosomal system is a fundamentally different molecular mechanism from the ubiquitin-mediated degradation of soluble proteins by the cytosolic proteasome (Sharpe *et al.*, 2014). While they both use a common pool of ubiquitin, part of the way these two ubiquitin-governed catabolic processes are segregated is by using different E2 conjugating enzymes and E3 ubiquitin ligases that catalyze different chain linkages (principally Lys48 polyubiquitin for proteasomal degradation).

To decode the ubiquitin-encoded lysosomal sorting information during intracellular sorting, a collection of sequentially assembled macromolecular complexes, designated the endosomal sorting complex required for transport-0 to -III (ESCRT-0–III), form a sorting hub upon the early endosome surface by recognizing PtdIns3P and (Lys63-containing) ubiquitin simultaneously (Piper *et al.*, 2014). The same guiding mechanistic principles apply: these are again modular peripheral membrane proteins composed of a run of folded units that can interact with specific, compartmentally restricted lipids, ubiquitin conformations, and each other. Recalling the geometry-influenced sorting that occurs in the early endosome (Figure 2), assembly of the ESCRT machinery provides a mechanism to enrich/trap transmembrane proteins within the bulbous vesicular portion of the developing early endosome as the thin sorting tubules are drawn out. Fundamentally, the ESCRTs represent patch of membrane that displays a distinct composition, dynamic and density compared with the adjacent, non-assembled membrane, which permits retention based on ubiquitin-chain instructions. A detailed description of the ESCRT apparatus and multivesicular body biogenesis is beyond the scope of this article, but more information can be found in other articles in this Encyclopedia.

Ubiquitin-Independent Downregulation of the LDL Receptor

The genetic basis for yet another (rare) hypercholesterolemic phenotype discloses a molecularly distinct but parallel pathway for posttranscriptional LDL receptor breakdown. It has emerged recently that a very minor fraction of dominant hypercholesterolemias is due, not to *LDLR* mutations, but to gain-of-function mutations in the gene encoding a putative protease designated proprotein convertase subtilisin/kexin type 9 (PCSK9) (Soutar and Naoumova, 2007; Horton *et al.*, 2009; Sharpe *et al.*, 2014; Leren, 2014). PCSK9 is a 692 amino acid secreted serine protease that undergoes autocatalytic cleavage of the nascent zymogen form during biosynthesis and transport along the secretory pathway (Table 1 and Figure 3). As for VLDL, the liver seems to be the primary site of production of the PCSK9 coursing through the plasma (Horton *et al.*, 2009). Population studies, analogously to *IDOL*, illustrate that gain-of-function (D374Y/H, F216L, and S127R) or loss-of-function (missense and nonsense mutations, including rare homozygous null individuals) PCSK9 alleles occur in human subjects, which co-segregate well with plasma LDL-cholesterol levels (Soutar and Naoumova, 2007; Horton *et al.*, 2009; Sharpe *et al.*, 2014; Leren, 2014).

The way that PCSK9 affects plasma LDL levels is largely by driving hepatic clearance of normal LDL receptors. Yet this mode of regulation is obviously quite distinct from IDOL-mediated ubiquitination, because PCSK9 does not operate in the cytosolic compartment – it is released from cells in exocytic vesicles and binds to the extracellular region of cell-surface LDL receptors. Newly synthesized PCSK9 exhibits a very short (minutes) circulatory half-life, testifying to the fact that once bound to the LDL receptor, the 1:1 stoichiometric complex swiftly winds up in the lysosome compartment for degradation (Soutar and Naoumova, 2007; Horton *et al.*, 2009; Sharpe *et al.*, 2014; Leren, 2014). And despite the catalytic potential of PCSK9, in the plasma the protein acts as an enzymatically inactive regulator of LDL receptor abundance that reprograms the trafficking itinerary of the bound receptor. This is because the cleaved but folded prodomain portion, which remains non-covalently attached to the mature protein, is positioned to conceal the catalytic triad (Horton *et al.*, 2009; Leren, 2014). Some (but not all) of the pathophysiological gain-of-function PCSK9 alleles encode a protein that binds to the LDL receptor with considerably higher affinity. The beneficial loss-of-function alleles cause hypocholesterolemic profiles because apparently they extend the normal half-life of the LDL receptor in the liver, improving cholesterol elimination from the plasma.

The FDNPVY signal and the core coat machinery that oversees the routine internalization of the LDL receptor (Dab2, ARH, clathrin) are generally still required for LDL receptor internalization after PCSK9 engagement at the cell surface (Horton *et al.*, 2009; Sorrentino and Zelcer, 2012; Soutar and Naoumova, 2007). Importantly, PCSK9 does not trigger ubiquitination of the LDL receptor. A lysineless mutated cytosolic domain form of the LDL receptor is still down-regulated by bound PCSK9, and the proteasome inhibitor MG139 has negligible impact on the kinetics of degradation of the LDL receptor in the presence of PCSK9 (Wang *et al.*, 2012). In fact, once in the endosomal compartment, redirection of the LDL receptor to the degradative lysosome by bound PCSK9 unexpectedly appears to occur quite independently of the intracellular domain of the receptor (Leren, 2014). Moreover, delivery of the LDL receptor to the lysosome is not contingent upon the canonical ESCRT-0/-I machinery (Wang *et al.*, 2012) that is necessary for proper sorting of the IDOL ubiquitinated receptor (Scotti *et al.*, 2013; Sorrentino *et al.*, 2013b).

How then does an extracellularly bound PCSK9 alter the fate of the LDL receptor in the sorting endosome? A hint for understanding this conundrum comes from the reduced cellular abundance of the Class 5 *LDLR* mutants – these defective proteins traffic to the lysosome locked to their LDL particle ligand (Hobbs *et al.*, 1990), as do normal mature forms of the LDL receptor complexed with polyclonal anti-receptor antibodies (Anderson *et al.*, 1982). Circulating PCSK9 interacts directly with the EGF-precursor-homology region on the luminal side of the LDL receptor. Alone, the inactive catalytic domain of PCSK9 attaches specifically to the EGF-A module, and this interaction is sufficient for internalization of PCSK9 together with the LDL receptor. Yet, in this setting, the half-life of the LDL receptor is not reduced because the molecular interaction between the PCSK9 catalytic domain and EGF-A is

sensitive to pH-induced dissociation within the endosome lumen (Leren, 2014), just like the interaction with apoB100. The structural basis for the binding of PCSK9 to EGF-A reveals a similar Ca^{2+} dependence (Andersen and Moestrup, 2014), accounting for the acidification-associated release, as discussed for the LA repeats and apoB100 above.

Paradoxically, the affinity of mature, full-length PCSK9 for the extracellular portion of the LDL receptor increases (> 100 fold) in a mildly acidic environment. An appealing view is that it is the less highly conserved C-terminal domain of PCSK9, which binds to the LA repeats of the LDL receptor ectodomain (Leren, 2014), that functionally diverts the bound receptor from recycling toward degradation. The LA repeats are needed for PCSK9 to orchestrate the redirection of the LDL receptor, implying that they play a role in counteracting the acid-triggered detachment of the PCSK9 catalytic domain from the EGF-A repeat. Because the C-terminal domain of PCSK9 is the least phylogenetically conserved portion of the protein, general electrostatic attraction that is pH enhanced, as opposed to tailored binding of co-evolved interaction surfaces, seems to be involved. The C-terminus of PCSK9 is also rich in surface exposed histidine residues that can add pH-responsive positive charge for effective salt bridging with of the negatively charged LA repeat Ca^{2+} cages. Further evidence for an important role of the C-terminal domain of PCSK9 is that neutralizing antibodies directed against this region counteract the normal degradative activity of the convertase (Leren, 2014); this represents a promising new avenue for the treatment of hypercholesterolemia. Altogether, it seems highly likely that the interaction of PCSK9 with the LDL receptor in an acidic environment prevents the receptor ectodomain assuming the closed compact conformation that promotes recycling. While residing within the vesicular region of the sorting endosome, proteolytic cleavage of extracellular bulk of the LDL receptor, liberating the ectodomain into the lumen, may further favor passage to the late endocytic compartment at the expense of recycling (Leren, 2014).

One curious fact is that PCSK9 mRNA is upregulated, in parallel with the LDL receptor, when cellular cholesterol levels fall. At first glance, this seems counterintuitive because, once secreted from the liver, PCSK9 will drive the rerouting of the receptor, increasing LDL receptor degradation in the lysosome compartment, decreasing the steady-state level and restricting bulk LDL uptake capability. This genetically programmed transcriptional response actually complicates the effectiveness of cholesterol-lowering statin therapy. It may be, however, that the concurrent transcription and translation of the LDL receptor and PCSK9 driven by the sterol responsive element binding protein (Goldstein and Brown, 2009) reflects the fact that PCSK9 could be an important endoplasmic reticulum chaperone for the LDL receptor (Strom *et al.*, 2014), in addition to the aforementioned Boca and RAP proteins. Another possibility is that localized secretion of PCSK9 from hepatocytes biases just exocytosed nascent VLDL particles to enter the bloodstream instead of being immediately trapped and endocytosed by LDL receptors on the sinusoidal (basolateral) plasma membrane (Horton *et al.*, 2009). But if the latter mechanism is operative, it is not immediately apparent why PCSK9 evolved to guarantee the swift and irreversible destruction of the LDL receptors it engages.

Concluding Remarks

Since the seminal investigations in the Goldstein and Brown laboratory mapped out receptor-mediated endocytosis as a centerpiece of homeostatic sterol regulation in humans, the LDL–LDL receptor pathway has provided unrivaled insight into endocytosis and protein trafficking mechanisms. One is struck by the impressive mechanistic mutability that has evolved to precisely regulate the intracellular trafficking of this clearly clinically important nutrient receptor. The high degree of complexity of the regulatory interaction web is illustrated schematically in Figure 5. The network is characterized by multiple routes of feedback inhibition when cholesterol levels are elevated, and by positive feedback when cellular levels of the sterol drop. Opposing and parallel layers of transcriptional and posttranscriptional regulation of LDL receptor abundance in cells allow heightened homeostatic responsiveness, but with

different kinetic signatures. As has been the case over the past several decades, it is highly probable that the type of sterol-dependent regulatory mechanisms delineated for the LDL receptor pathway will be broadly applicable to other cell membrane proteins. To be anticipated is clearer appreciation of new and unexpected levels of further regulation. For example, there are over 150 independent reports of the vital Tyr807 residue being posttranslationally modified to phosphotyrosine in high-throughput mass spectrometry databases (Hornbeck *et al.*, 2012). This modification to the [FY]XNPX [YF] signal, like vicinal ubiquitin conjugation by IDOL, will alter the recognition and hence trafficking information hardwired into the primary sequence of the LDL receptor. The identity of the tyrosine kinase(s) that phosphorylates the LDL receptor at Tyr807 is unknown, but could be responsible for uncoupling LDL traffic flow during acute signaling responses from the plasma membrane.

Figure 5 The LDL receptor protein interaction hub. An integrated hub-and-spoke depiction of the protein–protein and protein–lipid interactions that regulate LDL receptor trafficking operations and receptor half-life. Established molecular interactions are represented with a solid connecting line while presumed or likely interactions are shown with a broken line. HC: heavy chain; LC: light chain.

Retrograde Transport

L Johannes and C Wunder, Institut Curie, Paris, France

© 2016 Elsevier Inc. All rights reserved.

Introduction

Trafficking of vesicular carriers between the plasma membrane and endomembrane compartments is essential for transport of proteins and other macromolecules to diverse destinations inside and outside of the cell. Membrane trafficking is also required to assure the essential need of cells to maintain membrane homeostasis and to meet specific demands during development, signal perception, and transmission. Two major trafficking routes exist, comprising the endoplasmic reticulum (ER), the Golgi apparatus, and endosomes: the anterograde and retrograde pathways. Both are highly conserved in the eukaryotic kingdom, including plants and some protozoa, e.g., *Toxoplasma gondii*. The anterograde pathway delivers proteins and lipids in a vectorial manner from the ER to the plasma membrane. This outward flow of material is counterbalanced by various retrograde trafficking routes. Retrograde cargo proteins and lipids are endocytosed and transported to endosomes, before being delivered to the trans-Golgi network (TGN), and in some instances further to the ER.

The discovery of the retrograde trafficking pathway started in 1972 by studying the cellular intoxication process mediated by the plant toxin ricin (Olsnes and Pihl, 1972). Ricin is a highly toxic glycoprotein produced by the castor plant *Ricinus communis* and inhibits protein biosynthesis by modifying ribosomal ribonucleic acid (RNA) of toxin-exposed cells (Montanaro *et al.*, 1973). Later, Avrameas and colleagues found that even the Golgi apparatus was a trafficking station in the intoxication process of ricin (Gonatas *et al.*, 1975). Hence, the retrograde cargo protein ricin is binding to cell surface

glycoconjugates having nonreducing terminal galactose (ricin receptors), enters cells via endocytosis and reaches morphologically distinct Golgi membranes. Thus, the first step of the retrograde pathway was defined – trafficking from endosomes to the Golgi apparatus (Figure 1).

Scientists were searching for more than 10 years whether endogenous proteins would also use the retrograde pathway, as described by Olsnes for ricin. In 1985, a cellular protein – transferrin receptor – could be identified in leukemia cells by Snider and Rogers (1985), that also traffics from the plasma membrane to the TGN. This initial discovery was followed very soon by several other studies that used similar approaches based on Golgi-specific enzyme modifications. Of these, the characterization of mannose 6-phosphate receptor (MPRs) trafficking by Duncan and Kornfeld (1988) stood out. These authors provided first evidence for a model in which trafficking between endosomes and the TGN is part of the functional cycle of MPRs. Many lysosomal enzymes are post-translationally modified by mannose 6-phosphate residues. These are recognized by MPRs and shuttled from the TGN to endosomes. The unloaded receptors then return to the TGN for a new transport cycle (Figure 2).

Despite the discovery of several endogenous retrograde cargo molecules, toxins were used as discovery tools to study and understand this pathway further. Sandvig *et al.* (1992) showed for the first time in 1992 that another exogenous protein – the bacterial Shiga toxin (STx) – could reach the ER via the retrograde transport route, similar to ricin. As for ricin, the catalytic A-subunit of Shiga toxin is then translocated to the cytosol to inhibit protein biosynthesis by acting as a N-glycosidase, which cleaves a specific adenine nucleobase

Figure 1: Toxin entry into cells. Via different uptake routes, cholera toxin, Shiga toxin, and ricin reach early endosomes, from where they then traffic to the ER, via the Golgi apparatus. The catalytic A-subunits of these toxins are then retrotranslocated across the ER membrane to the cytosol where they can meet their molecular targets.

Figure 2 The role of retrograde transport in the cellular functions of Wntless and MPRs. Retromer is of critical importance for the trafficking of Wntless and MPRs from endosomes to the TGN as part of the cellular functions of these receptor molecules. See text for details.

from the 28S rRNA of the ribosomal 60S subunit (reviewed in Johannes and Römer, 2010).

These studies have laid the groundwork for the understanding of the trafficking behavior of a whole class of cytotoxic molecules, AB₅ toxins, for which no pore forming capacity could be demonstrated and that use the retrograde route to enter into cells (Figure 1). These toxins are named after their unique subunit composition, containing a single catalytic A-subunit and a homopentameric B-subunit composed of five B-fragments. In some cases, the A-subunit is covalently linked via a disulfide bridge to the B-subunit (Sandvig and van Deurs, 2002). The catalytically inactive B-subunit is binding to cell surface receptors and serves to mediate transport of the AB₅ protein complex from the cell surface to the lumen of the ER, via vesicular and tubular carriers and intracellular compartments. The B-subunit retains its binding capacity even in the absence of the A-subunit. However, the complete AB₅ holotoxin is required for mediating toxicity.

AB₅ toxins are a medically important class of bacterial exotoxins, which cause devastating human diseases. Prominent members of this class include the above-mentioned STx, which causes life-threatening diarrhea, dysentery, hemorrhagic colitis, and hemorrhagic uremic syndrome; *Escherichia coli* heat-labile enterotoxins and cholera toxin (CTx), which cause endemic and epidemic diarrhea and pertussis toxin (PTx), which is the causative agent for whooping cough (Beddoe et al., 2010). Each year, infections with bacteria that produce these toxins affect millions of individuals and cause more than a million deaths.

Many cellular functions in development and disease depend on the retrograde transport route, such as wnt morphogen gradient formation (Harterink et al., 2011; Yu et al., 2014; Figure 2), intracellular glucose (Esk et al., 2010), iron and copper ion homeostasis (Tabuchi et al., 2010), and glutamate receptor recycling (Zhang et al., 2012). Besides the poisonous effect of several toxins, the medical importance of the retrograde trafficking route was corroborated by many findings. Its dysfunction causes abnormal elevation of amyloid β -peptide

(Burgos et al., 2010); the nef protein of human immunodeficiency virus (HIV-1) favors immune-evasion by down modulating major histocompatibility complex (MHC) class I (Blagoveshchenskaya et al., 2002) and co-stimulatory molecules (Chaudhry et al., 2008). Recently, a new aspect in modulation of the retrograde pathway was discovered: the intracellular bacterium *Legionella pneumophila* is able to shut down the retrograde route in order to promote bacterial replication (Finsel et al., 2013). Taken together, understanding the retrograde trafficking pathway is important to develop efficient therapeutic strategies for a wide range of diseases.

Different Retrograde Pathways

The above-mentioned ground-breaking papers have proven the existence of a transport connection between plasma membrane/endosomes and TGN/Golgi/ER. The trafficking interface between endosomes and the TGN has become a subject of intense investigation in membrane biology research. The complexity of retrograde transport arises from different pathways between endosomes and the TGN. Endosomes are a complex membrane system of tubulo-vacuolar nature of which early endosomes and late endosomes/lysosomes are the major parts (Huotari and Helenius, 2011). There is an ongoing debate on whether these separate endosomal entities of different protein and lipid compositions are linked by vesicular carriers, or are transformed from one to the other by a process of maturation. Exactly how very early endosomes arise is not entirely clear, but it seems likely that membranes and volume are mainly derived from primary endocytic vesicles that fuse with each other. Very early endosomes receive cargo proteins through several endocytic pathways, including clathrin-mediated and clathrin-independent endocytic processes – caveolar, clathrin-independent carrier (CLIC) and ARF6-dependent pathways (Mayor and Pagano, 2007). Therefore very early endosomes are heterogeneous in terms of morphology, localization, composition, and function.

The identity and functional attributes of different endosomes is also defined by the association of cytosolic proteins to the cytoplasmic surface of the endosomal membrane (Huotari and Helenius, 2011).

Very early endosomes then converge into conventional early endosomes. Their limiting membrane contains a mosaic of tubular and vacuolar domains that differ in composition and function (Zerial and McBride, 2001). These include domains enriched in Rab5, Rab4, Rab11, Arf1/COPI, and retromer (Sonnichsen *et al.*, 2000; Bonifacino and Rojas, 2006). Domains located in the tubular extensions allow molecular sorting and generate transport carriers targeted to distinct organelles, including the plasma membrane, the recycling endosomes, and the TGN for retrograde trafficking (Bonifacino and Rojas, 2006). One of the cytosolic key players in retrograde trafficking is the retromer complex. This complex was shown to be involved in trafficking events from different endosomes to the TGN as well as for recycling to the plasma membrane (Temkin *et al.*, 2011). How specificity is achieved will be discussed later.

Pfeffer and colleagues were the first to pinpoint in 1993 an endosomal location from which the MPR recycles to the TGN: late endosomes (Lombardi *et al.*, 1993). In 1998, Johannes and colleagues reported that STx was not found on late endosomal membranes en route to the TGN, which led to the proposal that the toxin bypasses the late endocytic pathway altogether and directly traffics from early endosomes to the TGN (Mallard *et al.*, 1998). Recently, Lieu and Gleeson (2010) suggested that Shiga toxin might in part also traffic from recycling endosomes to the TGN. In summary, retrograde trafficking does occur from different endosomal sites (Figure 3). Routes from late, early, and recycling endosomes seem to operate in parallel. Below, we will discuss these three different scenarios individually. We list key molecular and morphological data that have helped to define them, and point out controversial matters whenever these exist.

Late Endosomes-to-TGN Trafficking

MPRs are the best characterized cargo proteins of the late endosomes-to-TGN retrograde transport process (Rohn *et al.*, 2000). More than 60 lysosomal hydrolases acquire a unique posttranslational modification in the Golgi complex: a mannose 6-phosphate residue, which enables them to bind to MPRs. Two types of MPRs have been identified, the cation-independent (CI-MPR) and the cation-dependent MPR (CD-MPR). Both carry newly synthesized precursor hydrolases from the Golgi to endosomes. MPRs release their ligands upon encountering the low pH of the late endocytic pathway. The receptors then return from late endosomes to the TGN to start another cycle of biosynthetic enzyme transport.

Cargo Sorting and Budding

Lysosomal hydrolase precursors are transported within the lumen of endocytic carrier vesicles to the lysosome for proteolytic activation. A multitude of sorting signals in the cytoplasmic tail of MPRs has been identified that ensure that MPRs are not lost into lysosomes where they would be degraded. A subset of these sorting signals is recognized by tail interacting protein of 47 kDa (TIP47), and strong arguments have been presented for a role of TIP47 in late endosomes-to-TGN trafficking of MPRs (Diaz *et al.*, 1997), even if some complexity has been noticed that may originate from TIP47's additional functions in lipid droplet formation (Bulankina *et al.*, 2009). TIP47 recognizes a phenylalanine-tryptophan motif in the cytoplasmic tail of CD-MPR (Diaz and Pfeffer, 1998), and a more complex domain of CI-MPR. TIP47 also binds Rab9•GTP, upon which its affinity for the CI-MPR is increased threefold (Carroll *et al.*, 2001). Rab9 is itself involved in the retrograde transport of MPRs (Riederer *et al.*, 1994). It has thus been suggested that TIP47 is a coat for MPR sorting into the retrograde pathway.

Figure 3 Sites of endosomal retrograde sorting in mammalian cells. Retrograde sorting can operate from different endosomal locations. See text for a detailed discussion of retrograde trafficking from early, recycling, and late endosomes.

Docking and Fusion

The Rab9 GTPase also binds to the GRIP domain golgin protein GCC185 (Golgi coiled-coil protein) (Reddy *et al.*, 2006) for which tethering functions have been suggested. Tethering is the process by which transport intermediates are captured on target membranes to allow for subsequent *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex formation and fusion. GCC185 is required for retrograde transport of MPRs (Reddy *et al.*, 2006; Derby *et al.*, 2007) and interacts with the SNARE protein syntaxin 16 that equally has key functions for retrograde transport from late (Ganley *et al.*, 2008) and early endosomes (see below). For the fusion of late endosomes-derived retrograde transport intermediates, syntaxin 16 is in a SNARE complex with syntaxin 10, Vti1a, and vesicle-associated membrane protein (VAMP3) (Ganley *et al.*, 2008).

Early Endosomes-to-TGN Trafficking

Mallard *et al.* (1998) provided first evidence for a direct transport route from early endosomes to the TGN, using Shiga toxin as a model cargo. This transport interface is used by other exogenous (cholera toxin) and endogenous (TGN38) cargo proteins (Ghosh *et al.*, 1998; Amessou *et al.*, 2007; Lieu *et al.*, 2007). Even MPRs may traffic directly from early endosomes to the TGN, in addition to using the late endosomes-TGN interface. Indeed, MPRs accumulate in early endosomes under many conditions that block retrograde trafficking to the TGN, i.e., depletion for the following proteins: retromer (Seaman *et al.*, 2013), the tSNARE syntaxin 10 (Ganley *et al.*, 2008), the clathrin adapter AP1 (Meyer *et al.*, 2000), the phosphatidylinositol 3-phosphate 5-kinase PIKfyve (Rutherford *et al.*, 2006), and the GRIP domain golgin GCC88 (Lieu *et al.*, 2007). Probably the multitude of sorting signals in the cytosolic tails of MPRs has evolved to permit recycling to the TGN from any stage of the endocytic pathway.

Cargo Sorting and Budding

Clathrin is localized on early endosomes and was shown to be required for the retrograde sorting of Shiga toxin (Saint-Pol *et al.*, 2004). In clathrin-depleted cells Shiga toxin perfectly colocalizes with transferrin receptor at times when the molecule has reached the TGN/Golgi in control conditions, demonstrating that the toxin needs clathrin to leave early endosomes. Different adapters have been identified that function with clathrin in retrograde sorting of Shiga toxin and/or other retrograde cargo proteins: AP1 (Meyer *et al.*, 2000), epsinR (Saint-Pol *et al.*, 2004), and oculocerebrorenal syndrome of Lowe (inositol polyphosphate 5-phosphatase) (OCRL) (Choudhury *et al.*, 2005). For some cargo proteins with acidic cluster motifs in their cytosolic tail, the phosphofurin acidic cluster sorting protein 1 (PACS1) appears to stabilize binding to AP1, and the CI-MPR accumulates in early endosomes upon overexpression of a dominant negative PACS1 (Scott *et al.*, 2006).

The retromer complex was identified first in yeast and then in mammalian cells. It has been shown that retromer is localized on the cytosolic leaflet of early endosomes and

required for retrograde transport. Retromer comprises two subcomplexes, a vps protein heterotrimer (Vps26, Vps29, and Vps35) and a sorting nexin (SNX) dimer. The vps heterotrimer binds cargo proteins (Seaman *et al.*, 2013). However, different cargo proteins are recognized by different vacuolar protein sorting (VPS) proteins of the retromer heterotrimer (A-ALP and Vps10p bind to Vps35p, CI-MPR shows bipartite interactions with VPS35 and VPS29, sortilin to VPS35, divalent metal transporter 1 (DMT1-II) to VPS35, and sorLA to VPS26).

The SNX subcomplex senses and/or generates curvature. Latest work from the Cullen laboratory indeed suggests a contribution of the sorting nexins to membrane bending, as purified sorting nexins were shown to deform and tubulate lipid vesicles (van Weering *et al.*, 2012). As such, retromer could function as a coat. However, retromer does not form the same type of electron-dense coats as observed for classical coatamer protein complex-I (COPI), coatamer protein complex-II (COPII), and clathrin. In addition, the molecular mechanism by which retromer sorts cargo seems to be distinct from that of classical membrane coats (Seaman *et al.*, 2013), but somehow similar to other endosomal sorting complexes, like the endosomal sorting complexes required for transport (ESCRT). Retromer seems to regulate trafficking of cargo proteins on non-flat membranes, rather within morphologically distinct tubulovesicular membranes, suggesting a novel mechanism of action. Furthermore, when retromer vps heterotrimer proteins are depleted, retrograde cargo-containing tubules still form that fail to detach from early endosomes (Popoff *et al.*, 2007, 2009). These findings suggest that vps retromer heterotrimer may play a critical role for scission. Whether this function is fulfilled via amphipathic helices/BAR-domains of SNX proteins, or indirectly via recruitment of a scission factor still needs to be determined. One possibility how retromer fulfills a scission function might be via its capacity to recruit the actin nucleation promotion factor Wiskott–Aldrich syndrome protein and scar homolog protein (WASH) and to drive the polymerization of actin on early endosomal membranes (Seaman *et al.*, 2013). A second hypothesis might be an indirect effect of the WASH complex, via the recruitment of dynamin-2 (Derivery *et al.*, 2009). Whether and how dynamin contributes to membrane scission on early endosomes in human cells has not yet been convincingly documented. In yeast, a dynamin-related protein, termed Vps1, promotes fission of SNX-coated retromer tubules on early endosomes (Chi *et al.*, 2014).

Important differences exist between the prototypical retromer in yeast and retromer in higher eukaryotes. A key difference is that, in mammalian cells, retromer is not a stable heteropentamer as in yeast, but a much more transient association of the cargo-selective trimer (Vps35, Vps26, and Vps29) and the Snx proteins (Snx1 or Snx2 with Snx5 or Snx6) (Seaman *et al.*, 2013). In addition, retromer exists in different subcomplexes, depending on which SNX protein is involved. In mammalian cells, SNX proteins indeed seem to determine the trafficking route and thereby the specificity of retrograde trafficking. Furthermore, many accessory retromer proteins that were identified from studies in higher eukaryotes are not conserved in yeast. The yeast retromer complex seems to function independent of the WASH complex. Thus, the exact

scope of functions of retromer accessory proteins is not clear at this stage.

Lipids also play critical roles in retrograde sorting. Notably the phosphatidylinositol lipids phosphatidylinositol 3-phosphate (Skånland *et al.*, 2007) and phosphatidylinositol 3,5-bisphosphate (Rutherford *et al.*, 2006) are directly involved in the membrane recruitment of sorting nexins, and may also affect retrograde sorting via Hrs (Popoff *et al.*, 2009). Furthermore, a redistribution of retromer components has been observed in glycosphingolipid-depleted cells (Raa *et al.*, 2009), in agreement with earlier studies that had found a role for raft lipids in retrograde sorting (Falguières *et al.*, 2001). By what mechanism mesoscale raft lipid organization affects the retromer complex, and whether specialized lipid domains are required for retrograde trafficking from early endosomes has yet to be determined.

Docking and Fusion

Early endosome-derived vesicles are trafficking further to the TGN, and this transport is microtubule dependent (Hehnl *et al.*, 2006). The Golgi-associated retrograde protein (GARP) complex was identified for tethering of MPR positive vesicles to TGN membranes (Perez-Victoria *et al.*, 2008). The GARP complex is recruited at the level of early endosomes, and then functions at the TGN to promote SNARE complex formation in interaction with syntaxin 6, syntaxin 16, and VAMP4 (Perez-Victoria and Bonifacino, 2009), three SNARE proteins that have previously been implicated in early endosomes-to-TGN trafficking (Mallard *et al.*, 2002). Other tethering factors for early endosomal retrograde cargo proteins are GCC88 and GCC185 (Derby *et al.*, 2007; Lieu *et al.*, 2007).

Recycling Endosomes-to-TGN Trafficking

In a comparative study it was found that depletion of the tethering factor GCC185 inhibited retrograde transport of Shiga toxin, but not that of the endogenous cargo protein TGN38 (Derby *et al.*, 2007), while the opposite was observed for the depletion of the tethering factor GCC85 (Lieu *et al.*, 2007). Since Shiga toxin, but not TGN38, could be detected in recycling endosomes under different experimental conditions, the authors concluded that TGN38 was transported directly

from early endosomes to the TGN, while Shiga toxin could also transit via recycling endosomes (Lieu and Gleeson, 2010). This conclusion is in apparent contradiction with earlier studies that had described the retrograde trafficking of TGN38 via recycling endosomes (Ghosh *et al.*, 1998), and it is difficult to reconcile with the established function of early/maturing endosomal retromer in the trafficking of Shiga toxin to the TGN. Furthermore, as mentioned above, recycling endosomes remain poorly defined in molecular terms, and whether they have evolved a truly independent retrograde sorting machinery, possibly involving Rab11 (Chaudhry *et al.*, 2008; Wilcke *et al.*, 2000) remains to be established.

Biophysical Mechanisms for Retrograde Trafficking

All trafficking events of proteins and lipids between distinct membrane-enclosed organelles are following the same mechanistic principles. The course of action per se for generic trafficking processes is as follows: cargo sorting, membrane bending and bud formation, scission in the neck region of the invaginated bud or tubule, and finally fusion of transport intermediates with acceptor organelles. In the following, we have summarized biophysical mechanisms of each of these steps, based on the list of established retrograde trafficking factors.

Membrane Bending

The exact mechanism of membrane bending for retrograde trafficking from early endosomes is not known. However, different SNXs bearing BAR-domains and/or amphipathic helices were analyzed by *in vitro* studies (van Weering *et al.*, 2012). Therefore, two SNX-driven mechanisms for membrane bending can be envisioned (Figure 4): (1) asymmetric insertion of amphipathic helices and/or (2) scaffolding by BAR-domain containing SNXs. Whether SNXs are able to form scaffolds at physiological concentrations such as to drive membrane deformation (Sorre *et al.*, 2012), still needs to be determined. Recently the concerted action of retromer SNXs and the WASH complex on tubule formation was supported by Seaman and colleagues (Freeman *et al.*, 2014). This report indicated the binding of RME-8 to retromer SNXs and the WASH complex

Figure 4 Membrane bending mechanisms in relation to SNX proteins. (a) Insertion of helices leads to asymmetric expansion of the cytosolic leaflet and to subsequent membrane bending. (b) BAR domain binding can serve to recognize membrane curvature (low BAR-domain protein concentration on membranes), or to drive membrane bending through a scaffolding effect (high concentration).

protein FAM21. Interestingly, clathrin could be localized to early endosomes (Popoff *et al.*, 2009; Esk *et al.*, 2010; Freeman *et al.*, 2014), and RME-8 also binds to the clathrin uncoating ATPase Hsc70 (Girard *et al.*, 2005). However, no reports currently exist on interactions between clathrin and components of the retromer machinery. Whether clathrin is directly involved in membrane deformation for other retrograde cargo protein requires further studies but seems likely when considering the function of the clathrin interactors AP1 (Meyer *et al.*, 2000; Natsume *et al.*, 2006), epsinR (Saint-Pol *et al.*, 2004), and OCRL (Choudhury *et al.*, 2005) in retrograde sorting on early endosomes.

Scission

The first indication for a molecular player for a scission process of endosomal tubules came from knock down experiments of vps retromer proteins (Popoff *et al.*, 2007, 2009). Endosomal tubules formed that failed to detach from early endosomes, pointing toward a function for retromer or retromer binding proteins in the membrane scission process. Recently, the WASH complex was discovered as a binding partner of retromer and a nucleation point for actin polymerization on early endosomes (Derivery *et al.*, 2009; Gomez and Billadeau, 2009). Pulling forces that are applied to the budding structure by molecular motors or polymerizing actin filaments are expected to reduce the energy barrier involved in neck or tubule fission (Liu *et al.*, 2006). However, even a reduced energy barrier may still require a dedicated scission factor to finalize the reaction. Several lines of evidence indicate that dynamin may provide this function. First, an interaction between WASH and dynamin was identified (Derivery *et al.*, 2009); second, the WASH complex was found at the base of extended tubules (Derivery *et al.*, 2009); third, dynamin inhibition induced extended long tubules on early endosomes (Mesaki *et al.*, 2011). A combined function of actin and dynamin on membrane scission in the retrograde route was recently postulated (Johannes *et al.*, 2014).

In summary, at least in human, a model can be proposed for the concerted action of different molecules within the same macromolecular complex. The VPS trimer recruits cargo and SNX proteins, which are deforming the membrane via a BAR domain-dependent scaffolding mechanism and assymmetric insertion of amphipathic helices. The RME-8 protein is recruited and to link the SNXs and the WASH subcomplexes for a concerted action in the scission process. WASH is able to initiate actin polymerization and to recruit dynamin.

Biomedical Applications of Retrograde Trafficking

Initially, bacterial toxins were used to eliminate cancer cells, or at reduced levels to alter cellular processes that control proliferation, apoptosis, and differentiation. Specificity for cancer cells was reached by coupling cytotoxic toxins to antibodies (immunotoxins) (Becker and Benhar, 2012). However, for most antibody-toxin conjugates clinical evaluation did not go beyond phase I trials for various reasons, mostly linked to toxicity and lack of efficacy.

Since several pathogens are using the retrograde pathway for the targeting of cytotoxic proteins into host cells, scientist

are developing tools to use the same pathway for pharmaceutical delivery (Tarrago-Trani and Storrie, 2007). Currently, three different applications of retrograde transport research can be identified (Tartour *et al.*, 2002; Moron *et al.*, 2004; Engedal *et al.*, 2011): the nontoxic B-subunits of AB₅ toxins can be used as carriers for cytotoxic drugs in cancer therapy, as carriers for imaging agents, or to deliver antigens to dendritic cells in order to trigger a therapeutic immune response.

Targeted Tumor Therapy

Altered glycosylation patterns of tumor cells are a universal feature in carcinogenesis, and may affect cell signaling, adherence, and motility (Hakomori, 1996). Remarkably, human cancers are often characterized by modified glycosphingolipid composition and metabolism, and several tumor-associated antigens have indeed been found to be glycosphingolipids (Hakomori and Zhang, 1997). The retrograde cargo protein STxB recognizes a specific glycosphingolipid, Gb3, which is highly expressed on human cancers (Garipey, 2001; Johannes and Decaudin, 2005; Engedal *et al.*, 2011). By following the retrograde route, STxB avoids recycling to the plasma membrane or degradation in the late endocytic pathway, which are features that may be of general interest in the development of innovative cancer targeting strategies (reviewed in Tarrago-Trani and Storrie, 2007). Since intratumoral injection of Shiga toxin inhibits tumor growth (Arab *et al.*, 1999; Ishitoya *et al.*, 2004), STxB might be an appropriate tool for targeted therapy.

Following intravenous injection or oral application in mice, STxB has indeed been shown to accumulate in adenocarcinomas of the digestive tract (Janssen *et al.*, 2006). A prodrug composition using the topoisomerase I inhibitor SN38 has been developed that is specifically activated in membranes of the secretory pathway that have been targeted from the outside of cells, via the retrograde route (El Alaoui *et al.*, 2007). Exploitation of this delivery modality may be particularly beneficial in therapeutic strategies requiring prolonged association of the prodrug with tumor cells to ensure efficient prodrug conversion to the active form.

Biomedical Imaging

Gb3 overexpressing cancer cells might be visualized by injecting nontoxic STxB molecules coupled to imaging agents (Janssen *et al.*, 2006; Viel *et al.*, 2008). The imaging agents are covalently coupled to the delivery tool and highlight Gb3 expressing cells. The following imaging agents were successfully coupled to STxB and delivered to tumors in mice: fluorescent STxB (Viel *et al.*, 2008), ¹⁸F-labeled STxB followed by Positron emission tomography (PET) imaging (Janssen *et al.*, 2006), and ultrasound contrast agents (Couture *et al.*, 2011).

Immunotherapy

Protein toxins have also been used to generate specific cytotoxic T lymphocytes (CTLs) against tumor antigens to which they have been linked chemically or genetically (Smith *et al.*, 2002). The function of the toxin-antigen conjugates is in this case to facilitate cytosolic entry of antigens, which are then degraded by

proteasomes and displayed on MHC class I molecules to prime a CTL response. This approach to generate therapeutic vaccines has been used with adenylate cyclase of *Bordetella pertussis* (Fayolle *et al.*, 1996), *Pseudomonas* exotoxin A (PEx A) (Donnelly *et al.*, 1993), *E. coli* bacterial heat-labile enterotoxin (Hearn *et al.*, 2004), and STxB (Haicheur *et al.*, 2000).

For example, antigens that are chemically coupled to STxB are selectively targeted to dendritic cells expressing the Gb3 receptor, and it has been shown that the MHC class I-restricted presentation of the vectorized antigens is proteasome- and transporter-associated with antigen processing (TAP) dependent (Haicheur *et al.*, 2000). This strongly suggests that the exogenous antigens are indeed delivered to the cytosolic compartment. In mice, the delivery of exogenous antigens to dendritic cells induces a potent cytotoxic T-lymphocyte response and protects the animals against experimentally induced tumor growth (Vingert *et al.*, 2006; Pere *et al.*, 2011; Badoual *et al.*, 2013; Sandoval *et al.*, 2013).

One could envisage the design of new synthetic molecules that interact with target cells similarly to the toxins discussed above, and mimic the toxin trafficking pathway to deliver molecules specifically to the Golgi or ER in order to correct enzymatic defects, or elicit toxicity for the treatment of cancer. Moreover, given its avoidance of the lysosome, perhaps this route could be of better use for gene delivery and enable prolonged survival of gene therapy vectors after targeted cell entry.

Introduction

There are hundreds of proteins that regulate diverse cellular functions via binding and hydrolyzing GTP molecules and are termed GTP-binding proteins (or G proteins for short) or GTPases. By alternating between GTP- and GDP-bound conformations, G proteins serve as molecular switches for regulation of essential cellular functions such as signal transduction, cytoskeleton organization, membrane trafficking, nucleocytoplasmic transport, cytokinesis, protein translation and translocation, etc. The GTP-bound form is biologically active in the sense that it interacts, recruits and/or activates effector proteins to promote the cellular functions. GTP hydrolysis converts the GTP-bound form to inactive GDP-bound form, which can be re-activated by GDP dissociation and GTP binding. This universal GTPase cycle is facilitated by guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs), which accelerate GDP dissociation and GTP hydrolysis in the cell, respectively. Rab proteins represent a large family of such G proteins and function in intracellular membrane trafficking. This overview discusses the structure and function of Rab proteins and several other well-studied G proteins to illustrate how G proteins control cellular processes.

Rab Family of G Proteins and Membrane Trafficking

Rab proteins were discovered in the budding yeast *Saccharomyces cerevisiae* in the forms of Ypt1 and Sec4 involved in different stages of exocytosis (Segev *et al.*, 1988; Salminen and Novick, 1987). It is now clear that Rabs are master regulators of vesicular transport of membranes and proteins in all eukaryotes from the last eukaryotic common ancestor (LECA) to mammals (Diekmann *et al.*, 2011; Elias *et al.*, 2012; Kloppe *et al.*, 2012). Vesicular transport is a fundamental mechanism that governs intracellular membrane trafficking on endocytic and exocytic pathways and involves budding and formation of vesicles from a donor compartment, movement of vesicles on cytoskeleton toward a target compartment, and fusion with the target compartment with the delivery of membrane and luminal cargoes (Sudhof and Rothman, 2009; Guo *et al.*, 2014). Rab proteins regulate each of these vesicular transport steps, via temporal interaction and recruitment of multiple effectors, which include cargo proteins to be packaged into the vesicles, motor proteins that facilitate the movement of vesicles along actin and microtubule cytoskeletons, and tethering factors that dock vesicles to target compartments for membrane fusion.

Human cells contain 66 Rabs, and each Rab is localized to a particular membrane compartment and controls a specific vesicular transport event between a donor compartment and a target compartment (Hutagalung and Novick, 2011; Li and Segev, 2012; Pfeiffer, 2013). For example, Rab5 is localized to

early endosomes and Rab7 to late endosomes on the endocytic pathway, whereas Rab2 is localized to the transport vesicles between the endoplasmic reticulum (ER) and the Golgi on the exocytic pathway (Chavrier *et al.*, 1990; Figure 1). The aforementioned Rabs are ubiquitously expressed in all tissues and control essential housekeeping transport functions, but there are Rabs that are tissue-specific and regulate specialized transport functions in a particular cell type, e.g., Rab3a and Rab27 in the exocytosis of synaptic vesicles and secretory granules in neurons, immune cells and skin cells, respectively (Darchen and Desnos, 2012; Figure 1).

Biosynthesis and Membrane Targeting of Rab Proteins

Rabs are small 20–30 kDa monomeric proteins made in the cytoplasm and contain two Cys residues at or near the C-terminus. Both Cys residues are posttranslationally modified by isoprenylation with the 20-carbon geranylgeranyl group, which provides the hydrophobic lipid anchor for targeting to the membrane. The Rab geranylgeranyl transferase that catalyzes the Rab isoprenylation is a multisubunit enzyme consisting of a Rab escort protein (REP) and a catalytic

Figure 1 Rabs localizing to distinct organelles in the cell. Some Rabs are ubiquitously expressed in all eukaryotic cells, for example, Rab5, Rab7, Rab1, Rab2, etc. that are localized to endocytic and exocytic compartments, while other Rabs are expressed only in specific cell types, for example, Rab3a and Rab27 that are localized on secretory vesicles in professional exocytotic cells. EE, early endosome; GSV, Glut 4 storage vesicle; LE, late endosome; LY, lysosome; RE, recycling endosome; SV, secretory vesicle; TE, transcytotic endosome.

heterodimer (Leung *et al.*, 2006). The REP recognizes and binds to conserved sequences in Rabs and the catalytic complex transfers the geranylgeranyl group. Some Rabs that end with a CxC motif are further modified by methylation at the C-terminal Cys residue. Once modified, the Rabs are delivered to the membranes by the REP. REP prefers GDP-bound to GTP-bound Rab by three orders of magnitude, indicating that Rabs are prenylated and delivered to the membrane mainly as GDP-bound form. Upon GDP dissociation and GTP loading at the membrane, which is facilitated by a GEF (Blumer *et al.*, 2013; Soldati *et al.*, 1994; Ullrich *et al.*, 1994), the GTP-bound Rab is stably associated with the membrane and can then interact with effectors to promote vesicular transport (Figure 2).

The specificity of membrane targeting by each Rab may be determined by the specific membrane localization of a cognate GEF for the Rab, although the association of GEFs with distinct membrane compartments is not completely understood. In addition, a GDP displacement factor (GDF) is shown to facilitate Rab membrane targeting to endosomes (Sivars *et al.*, 2003; Figure 2). Upon membrane association and GTP loading, the activated GTP-bound Rab then interacts with multiple effectors to facilitate packaging of cargo proteins into transport vesicles, movement of vesicles on actin and microtubule cytoskeleton, and vesicle fusion with the target compartment (Figure 2). The Rab functional cycle is completed by GTP hydrolysis, which is catalyzed by a GAP on the target membrane (Barr and Lambright, 2010), and recycling back to the

donor compartment, which is mediated by the GDP-dissociation inhibitor (GDI) (Soldati *et al.*, 1993; Garrett *et al.*, 1993; Ullrich *et al.*, 1993) (Figure 2). GDI is a protein homologous to REP and dissociates GDP-bound Rab from the target membrane by forming a Rab-GDI complex and protecting the geranylgeranyl groups. The Rab-GDI complex recycles via cytosol back to the donor compartment where a cognate GEF is located for GTP loading and activation of the Rab and a new round of Rab action (Figure 2). Unlike REP, GDI cannot associate with the Rab geranylgeranyl transferase.

Structure and GTPase cycle of Rab Proteins

Like other Ras-like small G proteins, Rab proteins contain a canonical GTP-binding domain consisting of five conserved sequence motifs G1-5, followed by a hypervariable region terminating with the C-terminal Cys motif that is post-translationally geranylgeranylated for membrane association as described above. The GTP-binding domain is folded in such a way that the G1-5 motifs are brought into proximity to form a GTP-binding pocket supported by a six-stranded β sheet and five α helices (Dumas *et al.*, 1999; Zhu *et al.*, 2004). The G1 motif GxxxVGKS/T is in the so-called phosphate-binding loop and forms extensive hydrogen bonds with the β and γ phosphate groups of GTP via backbone amide groups and the side chains of the conserved Lys and Ser/Thr residues. The G2 motif is represented by a highly conserved Thr residue that

Figure 2 Rab GTPase cycle coupled with membrane association and dissociation. GDP-bound Rabs are complexed with GDI in the cytosol and targeted to the donor membrane compartment. At the membrane, the Rab-GDI complex may initially interact with a GDF to facilitate GDI dissociation or directly interact with a cognate GEF for the Rab to release GDP, reload GTP and insert into the membrane. The active GTP-bound Rab can interact with the cytoplasmic domain of transmembrane cargo proteins to package them into transport vesicles where Rabs may interact with myosin or kinesin motors to facilitate vesicle movement on actin or microtubule cytoskeleton and subsequently interact with tethering factors to dock the vesicle onto the target membrane compartment to facilitate SNARE-mediated membrane fusion, with the delivery of membrane and cargo proteins to the target compartment. Then GTP hydrolysis occurs, accelerated by a cognate Rab GAP on the target membrane, converts active Rab-GTP to inactive Rab-GDP, which is extracted by GDI and recycled back to the donor compartment. Thus through spatial and temporal interactions with multiple effectors, Rabs regulate every aspect of vesicular transport.

coordinates Mg^{2+} for GTP binding and hydrolysis and is in the effector loop (switch I region), which interacts with effectors in a GTP-dependent manner. The G3 motif WDTAGQE is in the switch II loop, interacts with the γ phosphate of GTP and positions the attacking H_2O molecule for GTP hydrolysis. The G4 and G5 motifs (NKxD and ETSAK) interact with the guanine base of GTP and determine the nucleotide-binding specificity, which prefers GTP to ATP by several orders of magnitude in affinity.

The importance of G1-5 motifs in GTP binding and hydrolysis is reflected by well-documented mutations that dramatically affect both processes. The Ser/Thr to Asn mutation in the G1 motif is shown to abolish GTP binding as well as reduce GDP binding. As a result, the mutant is either nucleotide-free or GDP-bound in the cell and is able to sequester cognate GEFs and block endogenous Rab activation. Such a mutant is called a dominant negative Rab mutant and is a useful tool in the study of Rab functions in cells. Likewise, the Asn to Ile mutation in the G4 motif abolishes GTP/GDP binding and the nucleotide-free mutant is inactive and manifests dominant negative phenotype. In contrast, the Gln to Leu mutation in the G3 motif does not change GTP-binding but blocks GTP hydrolysis, and consequently the mutant is locked in active GTP-bound conformation. Such a mutant is called a constitutively active Rab mutant.

The GTP hydrolysis or GTPase cycle allows Rab proteins to alternate between active GTP-bound and inactive GDP-bound conformations. However, Rabs show high affinity for GTP and GDP (Kd in the nanomolar range) and weak intrinsic GTPase activity, which means slow rates in GDP dissociation and GTP hydrolysis. In the cell, both reactions in the GTPase cycle are facilitated by catalyzing protein factors such as GEFs and GAPs, respectively (Barr and Lambright, 2010; Figure 2).

Rab GEFs include diverse groups of proteins that do not share sequence or structural homology but show a general mechanism by displacing the switch I region, disrupting Mg^{2+} coordination, and stabilizing the nucleotide-free form of Rab proteins (Barr and Lambright, 2010). As such, the GEFs facilitate GDP dissociation and GTP loading on Rabs in the cell where GTP concentration is two orders of magnitude higher. Rab GAPs, in contrast, contain a TBC (Tre-2/Bud2/Cdc16) domain for catalysis of GTP hydrolysis (Barr and Lambright, 2010). The TBC domain contains conserved catalytic motifs IxxDxxR and YxQ from which the Arg and Gln side chains insert into the GTP-binding site on the Rab to stabilize the transition state for GTP hydrolysis in a so-called 'dual finger' mechanism (Pan et al., 2006).

The Rab GTPase cycle is coupled to Rab membrane association/dissociation cycle in the sense that GDP-bound Rab is delivered to a donor membrane compartment by GDI and is activated by a cognate GEF localized on the membrane to become GTP-bound. The GTP-bound Rab then interacts with multiple effectors to promote transport vesicle formation, vesicle movement on cytoskeleton, and vesicle fusion with a target membrane compartment where a cognate GAP catalyzes GTP hydrolysis to convert it to inactive GDP-bound conformation (Figure 2). The GDP-bound Rab dissociates from the membrane by GDI and recycles back to the donor compartment for a new round of function. Thus the Rab GTPase cycle is highly regulated by strategically located GEFs and

GAPs. In some cases, the GEF of a downstream Rab happens to be an effector of an upstream Rab on the same trafficking pathway, forming a Rab cascade where the upstream Rab recruits the GEF for activation of the downstream Rab to establish distinct Rab membrane domains. This Rab cascade principle was discovered in the budding yeast *S. cerevisiae* where the GEF of an exocytic Rab (Sec4) is also an effector of the upstream Rab Ypt32, and is recruited by Ypt32-GTP to the Golgi membrane for activation of Sec4 in exocytosis (Ortiz et al., 2002). It is now clear that the GEF-linked Rab cascades also exist along the endocytic pathway and in mammalian systems (Mizuno-Yamasaki et al., 2012; Nottingham and Pfeffer, 2009). In addition, a GAP can also link a Rab cascade where a downstream Rab recruits the GAP for inactivation of an upstream Rab to establish the boundary between the two Rab membrane domains (Mizuno-Yamasaki et al., 2012; Nottingham and Pfeffer, 2009). As such, the GEFs and GAPs effectively promote the transition from an early to a late membrane compartment along a transport pathway, and may possibly generate ultrasensitivity and 'all-or-none' switch-like behavior in the Rab activity (Li and Qian, 2003; Barr, 2013).

Effectors and Functions of Rab Proteins

In the active GTP-bound form on the membrane, Rabs can interact with and recruit multiple effectors to exert a number of functions in vesicular transport, including selection of cargo proteins into vesicles, vesicle movement on actin and microtubule cables, and tethering of vesicles to target compartment for membrane fusion (Figure 2).

Packaging Cargo Proteins into Transport Vesicles

It is well documented that some cargo proteins are Rab effectors and are selectively packaged into transport vesicles via interactions with the Rab proteins (Smythe, 2002). These cargo proteins are usually receptors and other transmembrane proteins. Their cytoplasmic domains contain sequence motifs for binding to the Rabs and such interactions are essential for selective packaging of the cargo proteins into transport vesicles. For example, the α subunit of $\beta 1$ integrins is an effector of Rab5 and Rab21 and is selectively packaged into Rab5- or Rab21-positive endocytic vesicles for recycling and remodeling of the plasma membrane during cell migration and cytokinesis (Pellinen et al., 2006, 2008). In addition, the angiotensin II Type 1A receptor ($AT_{1A}R$) is also a Rab5 effector and the interaction facilitates $AT_{1A}R$ endocytosis (Seachrist et al., 2002). On the exocytic pathway, Rab3b binds directly to polymeric IgA receptor (pIgR) to modulate its transcytosis in epithelial cells (van et al., 2002). In some cases, the Rabs do not directly interact with the cargo proteins but can still package them into transport vesicles via adaptor proteins that are Rab effectors. Such examples include Rab9-mediated recycling of mannose-6-phosphate receptor (M6PR) from late endosomes to *trans*-Golgi network (TGN) via the Rab9 effector TIP47 (Carroll et al., 2001) and Rab5-mediated recruitment of transferrin receptor into endocytic vesicles (McLauchlan et al., 1998).

Vesicle Movement on Actin and Microtubule Cytoskeleton

Another type of Rab effectors is the motor proteins including myosins, kinesins, and dyneins, which are recruited by the Rabs to transport vesicles to promote their movement on actin or microtubule cytoskeleton (Figure 2). These Rabs are usually on exocytic and recycling vesicles and they can bind to the C-terminal cargo-binding globular tail domain (GTD) of class V myosins whose N-terminal actin-binding motor domain may attach to actin cytoskeleton to facilitate vesicle movement toward the plasma membrane (Lindsay *et al.*, 2013). In addition, the Rabs can recruit microtubule-based kinesin and dynein motors directly or indirectly via effectors for movement on microtubule cytoskeleton (Horgan and McCaffrey, 2011). The kinesins include KIF20A and KIF16B that are plus-end microtubule motors and direct the transport vesicles toward cell periphery, whereas dynein is a minus-end microtubule motor and moves the vesicles toward perinuclear region at the center of the cell.

Tethering and Docking Transport Vesicles to Target Membrane Compartment

SNARE-mediated membrane fusion between a transport vesicle and a target compartment completes a vesicular transport event with the delivery of luminal and membrane cargoes to the latter compartment. In the cell, this process is facilitated by active Rab proteins and a group of Rab effectors called tethering factors that tether and dock transport vesicles to target compartments to bring the v-SNAREs on vesicles and the t-SNAREs on target compartments into proximity to form *trans*-SNARE complexes for fusion (Figure 2). These tethering Rab effectors include long coiled-coil homodimers and large multi-subunit complexes (Kummel and Ungermann, 2014), and they are recruited by the Rabs to the membranes to link a vesicle to a target compartment and can also interact with the SM (Sec1-Munc18) proteins to facilitate the assembly of SNARE complexes. As such, Rab proteins are essential for the efficiency of membrane fusion in vesicular transport (Ohya *et al.*, 2009).

Other Rab Effectors

A Rab can interact with multiple effectors, which may be exemplified by the identification of over 20 Rab5 effectors that bind specifically to GTP-bound Rab5 in pull-down assays (Christoforidis *et al.*, 1999). In addition to the effectors that directly participate in vesicular transport, some effectors play a regulatory role. For example, some GEFs and GAPs are also effectors of upstream and downstream Rabs that get recruited to the membrane to establish Rab cascades as described above. Another example is the Rab5 effector Rabaptin-5, which forms a complex with and recruits Rabex-5 (a Rab5 GEF) to the membrane via binding to active Rab5-GTP. As a result, the Rabaptin-5 and Rabex-5 complex can activate more Rab5 molecules on the membrane in a positive feedback loop to recruit additional Rab5 effectors to create and maintain a functional Rab5 membrane domain (Horiuchi *et al.*, 1997; Zhu *et al.*, 2010). Furthermore, the Rab5 effectors APPL1 and APPL2 play an important role in signal transduction by

recruiting Akt and regulating its substrate specificity, which is critical in zebrafish development (Schenck *et al.*, 2008). Recently Rab effectors are also shown to regulate autophagy (Szatmari and Sass, 2014). One such example is the class III PI 3-kinase (Vps34) that is an effector of both Rab5 and Rab7 (Murray *et al.*, 2002; Stein *et al.*, 2003) and is recruited to endosomes to produce PI3P and promote autophagosome formation during autophagy. In addition, an effector of the exocytic Rab1/Ypt1, TRAPP1 complex, is well documented for its role in the initiation of autophagy by promoting the formation of preautophagosomal structure (PAS) (Barrowman *et al.*, 2010; Lipatova and Segev, 2012).

Other G Proteins

In addition to the Rab proteins, there are hundreds of G proteins, large and small, that utilize the universal GTP hydrolysis cycle to control the efficiency, fidelity and directionality of diverse cellular functions via specific intracellular localization and interaction with distinct effectors. Such G proteins are everywhere in the cell and some well-documented examples are described below.

Ras Superfamily of G Proteins

The Rab family represents the largest branch of the Ras superfamily of small G proteins, which consists of Ras proteins, Rho proteins, Arf proteins and Ran protein in addition to the Rab proteins (Cox and Der, 2010). These 20–30 kDa monomeric G proteins share a similar structure, with a conserved GTP-binding domain at the N-terminus followed by a hypervariable domain at the C-terminus. The Ras and Rho proteins, like the Rab proteins, contain a C-terminal Cys motif that is modified by isoprenylation. The Ras proteins are modified by the 15-carbon farnesyl group, whereas the Rho proteins are mostly modified by the 20-carbon geranylgeranyl group. H-Ras and N-Ras proteins but not K-Ras also contain palmitoylation at upstream Cys residues to increase further the hydrophobicity for association with the plasma membrane. The Arf proteins also contain lipid modification, but it occurs at the N-terminal Gly residue by myristoylation. These lipid modifications provide the hydrophobicity necessary for the G proteins to associate with the membranes. In contrast, The Ran protein contains no lipid modification, and it is soluble and plays a role in nucleocytoplasmic transport of proteins and RNAs through nuclear pores.

Ras proteins are localized to the plasma membrane of cells and function as a critical molecular switch in controlling growth factor-mediated signal transduction pathways and cell growth and proliferation (Colicelli, 2004; Cox and Der, 2010). In this case, growth factors such as epidermal growth factor (EGF) bind to their cognate receptors on the cell surface causing conformational changes and activating the tyrosine kinase in the cytoplasmic domain. The resulting phosphorylation of Tyr residues in the receptor cytoplasmic domain leads to recruitment of adaptors and a Ras GEF to activate Ras, i.e., conversion of Ras-GDP to Ras-GTP, and recruitment of Ras effectors for signal transduction. A well-known Ras-mediated signal transduction pathway is the so-called mitogen-activated

protein kinase (MAPK) cascade that ultimately leads to phosphorylation of nuclear transcription factors, activation of target gene expression and cell proliferation. The Ras effector that triggers this phosphorylation cascade is Raf protein, a MAPK kinase kinase (MAPKKK), which phosphorylates and activates MEK protein, a MAPK kinase (MAPKK), which in turn phosphorylates and activates a MAPK that subsequently moves to the nucleus to phosphorylate and activate the transcription factors. In addition, there are other Ras effectors such as PI 3-kinase, RalGDS, RIN, MEKK-1, PKC, Nore and AF6, which may temporally and/or spatially contribute to the regulation of cell proliferation and differentiation. Mutations in the GTP-binding domain of Ras can lead to defects in GTP binding or hydrolysis, and produce dominant negative or constitutive active Ras phenotype. For its important role in regulation of cell growth and proliferation, constitutive active Ras mutations are frequently found in a variety of cancers such as colon cancer, pancreatic cancer, lung cancer, etc. and indeed Ras is the first human oncogene discovered in the early 1980s.

Rho proteins are well known regulators of actin cytoskeleton, including Rho isoforms, Rac proteins, and Cdc42 (Ridley, 2012). Like other small G proteins, they are activated by GEFs and inactivated by GAPs, and their membrane association is regulated by Rho GDIs that keep the proteins in inactive GDP-bound state in cytosol. Once in the active GTP-bound state, Rho, Rac and Cdc42 promote the formation of distinct actin structures in the cell including stress fiber, lamellipodium, and filopodium, respectively. The Rho effectors, ROKs and mDia, may play a role in stress fiber formation by interaction with actin-binding proteins such as myosin and profilin, respectively. Lamellipodia are plasma membrane ruffles formed by *de novo* actin polymerization, and the Rac effector WAVE complex may regulate lamellipodia formation via the Arp2/3 protein complexes. Filopodia are long protrusions of plasma membrane caused by directed actin polymerization and cross-linking via actin-binding proteins, and the Cdc42 effectors, PAKs and WASPs, may regulate filopodia formation. Because of their important role in actin organization, Rho proteins in general are involved in integrin-mediated focal adhesion complex formation for interaction with extracellular matrix and cadherin-mediated cell-cell junctions for intercellular communication. As such, they contribute to cell polarization and migration. In addition, Rho proteins are known for regulation of endocytosis and phagocytosis as well as target gene expression and cell cycle progression.

Arf proteins are essential for recruitment of coat proteins and budding/formation of transport vesicles during vesicular transport (D'Souza-Schorey and Chavrier, 2006; Donaldson and Jackson, 2011; Gillingham and Munro, 2007). In the inactive GDP-bound conformation, the N-terminal myristyl group is buried inside and the protein is cytosolic. Upon activation by membrane-associated GEFs, the GTP-bound form releases the myristyl group and inserts into the membrane. Unlike Rab and Rho proteins, there is no Arf GDI to regulate membrane association and dissociation. The Arf function in coat assembly and vesicle formation may be exemplified by Sar1, a member of the Arf family discovered in yeast. Sar1-GTP on the ER membrane recruits the COPII coat consisting of Sec23p-Sec24p and Sec13p-Sec31p complexes, which induce

membrane curvature to promote vesicle budding off the membrane (Antonny *et al.*, 2001). Arf1 plays a similar role in vesicle formation on the Golgi membrane via recruiting the COPI coat. The biochemical activities of Arf proteins involve stimulation of ADP-ribosylation of the α subunit of heterotrimeric G proteins by cholera toxin (Kahn and Gilman, 1986), which is how Arfs were discovered, and activation of phospholipase D (Brown *et al.*, 1993), which produces phosphatidic acid and activates PI 5-kinase to alter membrane lipid composition in such a way that facilitates vesicle formation. In addition, the Arf family contains a number of Arf-like (Arl) proteins that show Arf-like structure but not the ADP-ribosylation activity (Kahn *et al.*, 2006). Arl proteins may also play an important role in membrane trafficking, especially at the Golgi complex. For example, Arl1 can recruit multiple effectors to the TGN, including GRIP domain-containing proteins, a GGA protein, an ArfGEF and a flippase (Singer-Kruger *et al.*, 2008; Tsai *et al.*, 2013; Gillingham and Munro, 2007), to facilitate the membrane trafficking process. In addition, several Arl proteins (Arl3, Arl6, Arl8) are suggested to be involved in regulation of microtubule-based functions such as cilogenesis (Kahn *et al.*, 2005; Donaldson and Jackson, 2011).

Dynamin

Parallel to Arf-mediated vesicle formation on the ER and Golgi membranes, dynamin is well documented for its role in vesicle formation on the plasma membrane as well as at the TGN (Jones *et al.*, 1998; Kessels *et al.*, 2006; Schmid and Frolov, 2011). Dynamin is a large multi-domain G protein, with a N-terminal GTP-binding domain followed by a α -helical middle domain, a pleckstrin homology (PH) domain, a GTPase effector domain (GED), and a C-terminal proline-arginine domain (PRD). Dynamin molecules can self-assemble into dimers and oligomers via the GED domain, and this self-assembly greatly accelerates dynamin GTPase activity via stabilization of G1 loop and switch regions and is essential for membrane fission at the plasma membrane to produce endocytic vesicles during clathrin-mediated endocytosis. Dynamin binds to the membrane via the lipid-binding PH domain and assemble to induce membrane curvature and invagination, followed by GTP hydrolysis to promote fission and vesicle formation and dissociation from the membrane. Recent studies suggest that dynamin is sufficient to produce vesicles from a lipid bilayer with lipid composition similar to the plasma membrane (Schmid and Frolov, 2011). For its function in membrane fission at the plasma membrane as well as at the TGN, dynamin may control the formation of both endocytic and exocytic vesicles and regulate multiple membrane trafficking pathways, including clathrin-mediated endocytosis, caveolae-mediated endocytosis, phagocytosis, macropinocytosis, and protein secretion (Praefcke and McMahon, 2004; Schmid and Frolov, 2011).

Heterotrimeric G Proteins

Heterotrimeric G proteins are well-known signal transducing proteins and consist of α , β and γ subunits, with α subunit being the actual G protein for GTP binding and hydrolysis (Tesmer, 2010; Hepler and Gilman, 1992). At resting state, the

α subunit is in inactive GDP-bound conformation complexed with β and γ subunits, and this trimeric complex is anchored to the plasma membrane via a number of lipid modifications, including myristoylation and/or palmitoylation of the α subunits and prenylation of the γ subunits. There is a large family of G protein-coupled receptors (GPCRs) with seven transmembrane domains that relay diverse extracellular signals such as hormones and growth factors to intracellular G proteins, which in turn activate various effectors and signal transduction pathways leading to physiological changes of cells. It starts with a ligand binding to a GPCR, and the ligand-bound GPCR functions as a GEF for activation of the G protein by stimulating the exchange of GDP for GTP. The GTP-bound α subunit undergoes conformational changes and dissociates from the GPCR as well as the $\beta\gamma$ complex. Both the α subunit and the $\beta\gamma$ complex can activate downstream effectors and promote signal transduction processes. GTP hydrolysis then converts the α subunit to inactive GDP-bound state, which reunite with the $\beta\gamma$ complex to form the trimeric G protein ready for a new round of GTPase cycle and signal transduction. The GTP hydrolysis reaction is accelerated by RGS (regulators of G-protein signaling) proteins (Berman and Gilman, 1998).

Based on α subunits, G proteins are classified into G_s , G_i , G_q , and G_{12} families that activate different effectors and signal transduction pathways (Neer, 1995). A well-known effector of G_s and G_i proteins is adenylyl cyclase, which is activated by the GTP-bound α subunits of G_s proteins but inhibited by those of G_i proteins. Adenylyl cyclase catalyzes the production of cAMP that is a second messenger for activation of cAMP-dependent protein kinases and induction of physiological changes in the cell. Among members of G_i proteins, the GTP-bound α subunit can activate cGMP phosphodiesterase for phototransduction in retinal rod cells, whereas the $\beta\gamma$ complex can activate a K^+ channel during acetylcholine-mediated signal transduction in cardiac cells. G_q proteins are known to activate phosphoinositide-specific phospholipase C, which produces inositol 1, 4, 5-triphosphate (IP_3) and diacylglycerol (DAG) as second messengers for mobilization of intracellular Ca^{2+} store and activation of protein kinase C, respectively, to induce physiological changes in the cell.

G Proteins in Protein Synthesis and Translocation

Protein synthesis occurs on ribosomes where triplet codons in mRNAs are translated into amino acid sequences in proteins. This is a complex process and involves initiation factors, elongation factors and releasing factors, many of which are G proteins, including bacterial initiation factor IF2, elongation factors Tu (EF-Tu) and EF-G, and releasing factor RF3 and their homologs in eukaryotes. Among them, EF-Tu is one of the best-characterized and forms a complex with aminoacyl-tRNA (aa-tRNA) in its active GTP-bound state to deliver the latter to the A site of the ribosome for addition of amino acid to the growing polypeptide chain (Maracci *et al.*, 2014). GTP hydrolysis by EF-Tu serves as a timer for proof-reading of incoming aa-tRNA so that only correct amino acid (cognate to the codon) is incorporated into the polypeptide chain (Thompson, 1988). In this regard, the GTPase activity of EF-Tu is greatly increased by the cognate aa-tRNA-codon recognition on the ribosome, which

thus functions as a GAP for EF-Tu. The resulting GDP-bound EF-Tu reduces affinity for aa-tRNA and ribosome and dissociates from the complex. EF-Tu is tightly bound to GDP and requires interaction with EF-Ts, a GEF, to release GDP and re-loading of GTP for a new round of delivery of aa-tRNA to the ribosome.

Protein translocation refers to the process of secretory proteins to move from the site of synthesis, i.e., ribosomes, into the lumen of the ER, which involves binding of a hydrophobic signal peptide on the nascent polypeptide to the signal recognition particle (SRP) that in turn binds to the SRP receptor (SR) in the ER membrane to facilitate the co-translational translocation process via the ER translocon (Egea *et al.*, 2005). Both SRP and SR are G proteins and protein translocation depends on their GTP hydrolysis cycle. In GTP-bound state, SRP docks onto SR to form a SRP-SR complex, and crystal structure of this complex suggests conformational changes to form a composite active site with twinned GTP molecules, which are hydrogen bonded to each other and contribute to each other's binding and hydrolysis. GTP hydrolysis triggers disassembly of the SRP-SR complex. In this interesting variation of G protein-mediated function, two G proteins in GTP-bound state form a complex, which is arranged in such a way that each G protein functions as a GAP for the other G protein to promote GTP hydrolysis leading to disassembly of this complex. Thus, the GTP binding and hydrolysis cycle of SRP and SR provide a spatial and temporal control for protein translocation into the ER.

Adaptor Proteins

Adaptors were originally defined as proteins able to link transmembrane cargo proteins to the membrane coat. This definition was implicitly expanded to also require binding to phospholipids and other elements of the trafficking machinery to incorporate cargo into and to facilitate the assembly of transport carriers. Whereas some adaptors have the ability to bind membrane, cargo, and coat proteins, others indirectly fulfill these requirements by interacting with bridging elements and consolidating the protein network (Table 1).

Heterotetrameric Adaptor Complexes

Assembly polypeptides (APs) or adaptins are a family of protein complexes involved in vesicle trafficking with five members (AP1–5) found in most eukaryotes (Bonifacino, 2004; Hirst *et al.*, 2013). APs are heterotetramers composed of two large subunits (~100 kDa, $\beta 1/\gamma$, $\beta 2/\alpha$, $\beta 3/\delta$, $\beta 4/\epsilon$, $\beta 5/\zeta$ in AP1–5 respectively), one medium (~50 kDa, $\mu 1$ –5), and one small subunit (~20 kDa, $\sigma 1$ –5) (Figure 1(a)). In addition, AP1–3 exhibit cell type-specific isoforms. While vertebrates and plants have all the 5 members of this family, only AP1–3 are present in flies, worms, and yeast (Hirst *et al.*, 2013). Surprisingly, while in multicellular organisms several APs are required for normal embryonic development, they are dispensable for survival and clathrin-mediated endocytosis (CME) in yeast (Mitsunari *et al.*, 2005; Huang *et al.*, 1999).

The large subunits consist of an N-terminal trunk domain, followed by an unstructured hinge domain and a C-terminal appendage domain (Collins *et al.*, 2002; Figure 1(a)). The N-terminal trunks together with the μ and σ subunits form the core of the AP complex. While the trunk domains of α , γ , δ , ϵ ,

and ζ subunits are involved in binding to target membranes, the μ and σ subunits are involved in cargo recognition. AP recruitment to membranes is facilitated by ADP-ribosylation factor (ARF) family of proteins in their membrane-bound, GTP-loaded state. While, Arf-6 primarily fulfils this function at the plasma membrane, Arf-1 does it at the *trans*-Golgi network (TGN) (Ren *et al.*, 2013). The hinge domains of the β subunits in AP1–3 have one or more L Φ X Φ [D/E] (L represents Leucine, X represents any amino acid, and Φ represents bulky hydrophobic amino acids, such as leucine, isoleucine, methionine, valine, and phenylalanine) motifs responsible for binding to clathrin (Owen *et al.*, 2004). However, $\beta 4$ and $\beta 5$ lack this sequence and thus AP4 and AP5 complexes were suggested to mediate clathrin-independent vesicle trafficking (Hirst *et al.*, 2013). The appendage domains serve as a platform for interacting with other adaptor and accessory proteins (Figure 1(b); Owen *et al.*, 2004). While the N-terminal domain of μ subunits contributes to the core, the C-terminal domain recognizes tyrosine-based sorting signals within cargoes.

AP complexes mediate the sorting of various transmembrane proteins, including type I, type II, and multi-span proteins. To recruit cargoes to vesicles, APs recognize short sorting signal sequences that reside in the cytosolic region, usually at 4–10 residues from the transmembrane domain. There are two well-characterized AP-targeting sorting signal sequences: tyrosine-based and leucine-based signals (Nakatsu and Ohno, 2003; Traub, 2009).

The tyrosine signal consists of four amino acids fitting the YXX Φ consensus, where Y stand for tyrosine. The medium μ subunits of AP complexes have been identified to play a central role in YXX Φ sequence recognition. The leucine-based signals recognized by APs fit into the [D/E]XXXL[L/ Φ] consensus, where the -4 position from the first leucine is either aspartic acid or glutamic acid, then followed by three non-conserved amino acids. This sequence motif precedes two

Table 1 Adaptor properties

Adaptor name	Clathrin (CBM)	AP2 (ABM)	Lipid – Adaptor binding domain	Example of cargo (signal) – Adaptor interacting domain/subunit	Other domains – binding partners	Localization
Classical heterotetrameric adaptor proteins recognizing YxxΦ and diLL signals						
AP1	+		PI4P – $\gamma, \beta 1$	CI-M6PR (YXXΦ)- $\mu 1$, (diLL)-[$\gamma/\sigma 1$]		TGN
AP2	+		PI(4,5)P ₂ , PI(3,4,5)P ₃ – $\alpha, \mu 2$	TfR (YXXΦ)- $\mu 2$, CD4 (diLL)-[$\alpha/\sigma 2$]		Plasma membrane
AP3	+		?	Lamp-1(YXXΦ)- $\mu 3$, Tyrosinase (diLL)-[$\delta/\sigma 3$]		Endosome
AP4	–		?	APP (YKFFE)- $\mu 4$		TGN
AP5	–		?	?		Late endosome
Adaptors for cargo carrying acidic DXXLL peptide						
GGA1,2,3	+		PI4P – GAT	M6PR(DXXLL)-VHS	GAT – Ub	TGN
Adaptors for ubiquitinated-cargo						
Epsin	+	+	PI(4,5)P ₂ – ENTH	VEGFR2 – UIM	NPF – Eps15	Plasma membrane
Eps15	–	+	PI(3,5)P ₂ – EH	EGFR – UIM	ESFGDGFADFSTLS – AP1	Plasma membrane
Eps15R	+		PI4P – ENTH	c-Met receptor – coiled coil Vtib-?	DFxD[F/W] – AP1	TGN
Adaptors for cargo carrying NPXY peptide						
Dab1	–	+	PI(4,5)P ₂ – PTB	ApoER2 (NPXY) – PTB		Plasma membrane
Dab2	+	+	PI(4,5)P ₂ – PTB	LDLR (NPXY) – PTB	NPF – Eps15	Plasma membrane
ARH	+	+	PI(4,5)P ₂ – PTB	LDLR (NPXY) – PTB		Plasma membrane
Numb	+	+	PI(4,5)P ₂ – PTB	APP (NPXY) – PTB	NPF – Eps15	Plasma membrane
Adaptors for GPCRs (Ser and Thr clusters)						
β -Arr	+	+	PI(4,5)P ₂	GPCRs – Arrestin fold		Plasma membrane
Adaptors for VAMPs						
AP180	+	+	PI(4,5)P ₂ – ANTH	Synaptobrevin2 – ANTH		Plasma membrane
CALM	+	+	PI(4,5)P ₂ – ANTH	Synaptobrevin2 – ANTH	NPF – Eps15	Plasma membrane

Notes: +, Motif present; –, Motif absent; ?, Not known; Φ, Hydrophobic amino acid; x, Any amino acid, single letter abbreviations of amino acids are used in the table above. Abbreviations: ANTH, AP180 N-terminal homology domain; ApoER2, Apolipoprotein E receptor 2; APP, Amyloid β precursor protein; CI-M6PR, Cation-independent mannose phosphate receptor; EGFR, Epidermal growth factor receptor; EH, Eps15 Homology; ENTH, Epsin N-terminal homology domain; GAT, GGA and Tom; GPCR, G-Protein coupled receptor; LDLR, Low-density lipoprotein 2; PIP, Phosphatidylinositol phosphate; PTB, Phosphotyrosine binding domain; TfR, Transferrin receptor; TGN, Trans-Golgi network; Ub, ubiquitin; VEGFR, Vascular endothelial growth factor; VHS – Vps27, Hrs and STAM.

leucines that lead to its 'dileucine signal' denomination. The first leucine cannot be replaced by any other amino acid, while the second can be substituted with a hydrophobic residue. In some proteins, the acidic residue at -4 position in the consensus can be replaced by a serine that upon phosphorylation acquires a negative charge and becomes functionally equivalent to the D/E residues. The dileucine signal is recognized by γ - $\sigma 1$, α - $\sigma 2$, and δ - $\sigma 3$ hemicomplexes of AP1–3 adaptors (Mattera *et al.*, 2011).

AP1

This adaptor is expressed ubiquitously and is essential during mammalian development (Meyer *et al.*, 2000). The AP1

gamma subunit interacts with the Golgi apparatus-enriched lipid phosphatidylinositol-4-phosphate (PI(4)P) and it is involved in cargo transport between the TGN and endosomal/lysosomal compartments (Wang *et al.*, 2003; Lefkir *et al.*, 2003). The localization of AP1 is also regulated by phosphorylation of its subunits, namely AP1 associates with membranes when the $\mu 1$ subunit is phosphorylated, whereas it detaches when $\beta 1$ is phosphorylated (Ghosh and Kornfeld, 2003). The cargoes of AP1 include furin, mannose-6-phosphate receptors (M6PR), and other proteins of the secretory pathway that are processed at the Golgi apparatus (Bonnemaizon *et al.*, 2013; Table 1). It has also been suggested that AP1 and Golgi-localized gamma-adaptin ear-containing Arf-binding proteins (GGAs) cooperate in cargo recruitment to clathrin-coated vesicles (CCVs) by recognition of sorting motifs on the

Figure 1 Heterotetrameric adaptor complexes. (a). Left panel: Cartoon representing the subunit organization of the AP1 complex as example of a heterotetrameric adaptin. Right panel: Subunit composition of known AP complexes. (b) Colocalization of AP2 with the monomeric adaptor Epsin2. HeLa cells expressing GFP-Epsin2 (green) were fixed and the presence of AP2 was revealed by indirect immunofluorescence using an anti-AP2 antibody (red). Scale bar: 20 μ m.

cytoplasmic tail of the cargoes (Bonnemaïson *et al.*, 2013). In fact, AP1 is believed to be a central player in CCV formation at the TGN affecting a wide variety of transmembrane proteins (Hirst *et al.*, 2012). Additionally, AP1 has also been linked to retrograde transport wherein several receptors were enriched in peripheral compartments upon AP1 depletion (Hirst *et al.*, 2012). The $\mu 1$ B subunit isoform specifically expresses in epithelial cells forming the AP1B complex which is involved in basolateral sorting of cargo such as the low-density lipoprotein receptor (LDLR) (Gonzalez and Rodriguez-Boulant, 2009). Mutations in AP1 have been linked to X-linked mental retardation (Tarpey *et al.*, 2006), MEDNIK syndrome (Montpetit *et al.*, 2008), and Pettigrew syndrome (Cacciagli *et al.*, 2014).

AP2

This adaptor is expressed ubiquitously and is essential for mammalian development (Mitsunari *et al.*, 2005). AP2 is capable of binding the plasma membrane-enriched lipids PI (4,5) P_2 and/or PI(3,4,5) P_3 and is a key element for CME. Upon recruitment to the plasma membrane, AP2 undergoes a conformational change from a 'lock' state to an 'open' state that exposes the clathrin-binding motif on the $\beta 2$ hinge (Collins *et al.*, 2002). The interaction of AP2 with cargo

stabilizes the open state, and thus facilitating formation and cargo inclusion in clathrin-coated pits (CCPs) (Kelly *et al.*, 2014). The α and β appendage domains interact with other clathrin adaptors and accessory proteins, such as Epsin, ARH, and AP180 to consolidate CCVs. The initial presumption that AP2 was essential for CME was challenged by the observation that although depletion of AP2 reduced CCV formation and specifically blocked transferrin-receptor internalization, epidermal growth factor receptor (EGFR), and LDLR internalization still progressed via CME (Motley *et al.*, 2003).

AP3

Organisms deficient in this adaptor survive to adulthood; however, they have defects in lysosome and lysosomal-related organelle biosynthesis (Yang *et al.*, 2000). AP3 membrane localization is similar to AP1, but with different degree of colocalization with clathrin, suggesting localization/functional differences (Peden *et al.*, 2004). Selective depletion of AP3 subunits resulted in indirect trafficking of lysosomal membrane proteins namely Lamp-1, Lamp-2, and CD63 via a plasma membrane-to-endosome pathway (Dell'Angelica *et al.*, 1999). The $\beta 3$ and $\mu 3$ subunits of the AP3 complex in metazoans have two isoforms: the isoform A is ubiquitously present, while the

isoform B is specifically expressed in neuronal and neuroendocrine tissues resulting in two AP3 complexes. The ubiquitous AP3A sorts its cargo (Lamp-1, Lamp-2, CD63) to the lysosome, while neuronal AP3B sorts its cargo (Chloride Channel-3, Vesicular glutamate transporter 1, vesicular GABA transporter, and many more synaptic proteins) to synaptic vesicles (Nakatsu and Ohno, 2003). Mutations in the ubiquitous AP3A complex results in Hermansky-Pudlak syndrome type-2, while mutations in the neuronal AP3B complex results in neurological symptoms such as epilepsy and hyperactivity (Badolato and Parolini, 2007; Nakatsu and Ohno, 2003).

AP4

This adaptor is also ubiquitously expressed in all tissues, but is not essential for development as evidenced by the existence of healthy knockout mice (Matsuda *et al.*, 2008). AP4 localizes to the TGN, but does not colocalize with AP1 perhaps due to the lack of CBMs (Hirst *et al.*, 2013). Notably, perturbation of CCV-assembly increased AP4 vesicle formation without changing the expression levels of AP4, suggesting a dynamic compensatory mechanism for TGN trafficking (Hirst *et al.*, 2012). Hence, AP4 is speculated to traffic at least some cargo also transported by CCV. Surprisingly, AP4 recognizes various types of sorting motifs on its cargoes, including canonical tyrosine motif on LDLR, YX[F/Y/L][F/L]E motifs on amyloid precursor protein (APP), FI (Phenylalanine-Isoleucine) motif on Furin, and unconventional basolateral sorting signal (EQFPHLAFWQDLG- (Bresciani *et al.*, 1997)) on M6PR (Simmen *et al.*, 2002). AP4 complex was required for the basolateral trafficking of these cargoes. Additionally, AP4 is also involved in basolateral trafficking in neurons where its cargoes are LDLR, AMPA (α -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid), and δ 2 glutamate receptors (Matsuda *et al.*, 2008). AP4-deletion showed aberrant accumulation of APP in TGN rather than in the endosomes implying a role for the AP4 complex in TGN-to-endosomes trafficking (Burgos *et al.*, 2010). Deficiency of AP4 in humans has been shown to cause intellectual disability and progressive spasticity that gradually develops to hereditary spastic paraplegia (HSP), suggesting that AP4 participates in human brain development (Hirst *et al.*, 2013).

AP5

This adaptor is the most recently identified, ubiquitous, heterotetrameric adaptor protein complex. Despite having less than 10% protein sequence identity with other APs, the secondary structure prediction of AP5 subunits is similar to the counterparts in other APs (Hirst *et al.*, 2013). AP5 does not associate with clathrin and was shown to localize on late endosomal compartments. Surprisingly, RNAi knock-down of AP5 resulted in cation-independent M6PR trapping in swollen early endosomes, albeit AP5 localization in late endosomes (Hirst *et al.*, 2013). AP5 endosomal trafficking route and cargoes are yet to be described. Mutations in AP5 ζ subunits, similar to AP4 subunits, lead to HSP. It is possible that the same cargo is transported by AP4 and AP5 at different points along the vesicle trafficking pathway.

Figure 2 Monomeric adaptors. Domain/motif organization of several monomeric adaptor complexes is shown. ABM, AP2-Binding Motif; ANTH, AP180 N-terminal Homology domain; Arr, Arrestin fold; CBM, Clathrin-binding motif; EH, Eps15 homology domain; ENTH, Epsin N-terminal Homology domain; GAE, Gamma-adaptin ear homology domain; GAT, GGA and Tom; NPF, Asparagine (N)-Proline (P)-Phenylalanine (F) peptide; PTB, Phosphotyrosine binding domain; UIM: Ubiquitin interacting motif; VHS, Vps27, Hrs, and STAM.

GGAs

GGAs were identified in early 2000s, and as their name indicates, they are localized at the Golgi apparatus (TGN), but they can also be found on endosomes (Ghosh and Kornfeld, 2004). GGAs are ubiquitously expressed and evolutionarily conserved, with three GGAs in human and mouse, two in yeast, and one in nematode and fruit fly. The existence of distinct GGA functions of the three GGAs has been demonstrated in mouse models. GGA2 null mice are embryonic or neonatal lethal; double mutant of GGA1 and GGA3 result in neonatal lethal, indicating that GGAs are required for developmental process and not fully redundant (Govero *et al.*, 2012). There are four folding modules in GGAs, from N-terminal to C-terminal: VHS (Vps27, Hrs, and STAM), GAT (GGA and Tom), hinge, and GAE (gamma-adaptin ear homology) domain (Figure 2).

The GAT domain has an N-terminal α -helical hook sub-domain which interacts with Arf-1 and consequently is recruited to the TGN (Collins *et al.*, 2003; Shiba *et al.*, 2003). Like the hinge region of β subunits in AP1–3, the hinge region of GGAs also contains an L Φ X Φ [D/E] CBM, that allows the GGAs to bind clathrin (Bonifacino, 2004). This indicated that GGAs are involved in CM-trafficking from the TGN. The C-terminus of the GAT domain binds ubiquitin and has been implicated in sorting of ubiquitinated-(Ub)-cargo from TGN to the vacuole in yeast (Prag *et al.*, 2005). The role of GGAs in trafficking Ub-cargo in mammals has not been fully explored.

GGAs also recognize cargo via the VHS domain which binds a DXXLL motif located in the cytosolic tail of the transported proteins, called acidic-cluster-dileucine signal. The motif consists of an aspartate residue followed by two leucines

at the third downstream position (Puertollano *et al.*, 2001; Doray *et al.*, 2002). The D and dileucine bind to the sixth to eighth α -helices of VHS where an electropositive pocket and two hydrophobic pockets reside (Misra *et al.*, 2000; Shiba *et al.*, 2002). In addition, acidic-cluster-dileucine signals also have been found in the hinge region of human GGA1 and GGA3, suggesting the formation of intramolecular complexes competing with cargo recognition; i.e., with auto-inhibitory properties (Bonifacino, 2004). The cargoes trafficked by GGAs include M6PRs and Sortilin (Puertollano *et al.*, 2001; Hirst *et al.*, 2012). Notably GGAs and AP1 cooperate for the trafficking of M6PR from the TGN to the lysosome. The GAE domain homologous to the γ -adaptin ear of AP1, also serves as a platform for binding to other endocytic accessory proteins with a DFGX Φ motif, namely γ -synergins, p56, Rabaptin 5 and Clint/EpsinR in mammals (Bonifacino, 2004). In addition, evidence showed the involvement of GGA1 in the retrograde trafficking of β -site APP-cleaving enzyme 1 from endosomes to the TGN while GGA3 plays a role in the targeting of BACE1 to the lysosomes (Tan and Evin, 2012).

The Epsin and Eps15 Families

The Epsin Family

These endocytic adaptors including Epsin and EpsinR are highly conserved in yeast and most vertebrates (Sen *et al.*, 2012). There are three Epsin paralogs in humans (Rosenthal *et al.*, 1999; Chen *et al.*, 1999; Spradling *et al.*, 2001). While Epsin-1 and 2 are ubiquitously expressed, Epsin3 has a more restricted expression pattern being confined to migratory keratinocytes, stomach cells, and cancer cells (Rosenthal *et al.*, 1999; Chen *et al.*, 1999; Coon *et al.*, 2011; Spradling *et al.*, 2001).

The N-terminus of Epsins has a highly conserved Epsin N-terminal homology domain (ENTH) (Figure 2) that binds PI(4,5)P₂, a lipid enriched at endocytic and signaling sites (Sen *et al.*, 2012). This interaction triggers a conformational change in the ENTH domain resulting in the formation of an additional α -helix, helix 0 which inserts into the plasma membrane inducing membrane curvature (Ford *et al.*, 2002). This structural transformation of the ENTH domain is believed to constitute the initial step of membrane invagination required for the formation of CCPs (Horvath *et al.*, 2007; Legendre-Guillemin *et al.*, 2004).

C-terminal to the ENTH domain is an unstructured region containing multiple motifs required for engaging cargo and endocytic machinery. Each Epsin has two or three UIMs (ubiquitin interacting motifs) able to bind ubiquitinated-cargo (Madshus, 2006). Epsins also bind clathrin via 1 (e.g., yeast) or 2 (e.g., mammalian) clathrin-binding motifs (CBMs) with the consensus L Φ Z Φ Z, where L is leucine, Φ is any hydrophobic residue, and Z is any polar residue. In higher eukaryotes, the CBMs flank 3–8 DP[W/F] (aspartate, proline, and tryptophan/phenylalanine) repeats that bind to AP2 (Figure 1B). Lastly, the C-terminus houses 2–3 NPFs (asparagine, proline, phenylalanine) which bind to Eps15 homology (EH) domain containing proteins, namely Eps15 and REPS1/2. In fact, Eps15 and Epsin together have been implicated in EGFR internalization (Sigismund *et al.*, 2005).

EGFR is a receptor tyrosine kinase belonging to the ErbB family which plays a major role in proliferation and differentiation. Interestingly, two different routes have been proposed for Epsin-bound activated EGFR. Classical route entails EGFR ubiquitination and recruitment to CCPs for internalization (Bertelsen *et al.*, 2011; Hawryluk *et al.*, 2006). However, at high EGF concentrations, a clathrin-independent, Eps15- and Epsin-dependent internalization was also found (Sigismund *et al.*, 2005). Interestingly, it has been reported that Epsin binding to ubiquitin negatively regulates clathrin binding (Chen and De Camilli, 2005), supporting the existence of an Epsin-mediated clathrin-independent route. Notably, the fate of EGFR differs based on the internalization route, wherein the clathrin-dependent route and the clathrin-independent route favor recycling and degradation of the EGFR receptor, respectively (Sigismund *et al.*, 2005).

While Epsin can contribute to EGFR signaling termination, it is required for activation of the notch signaling pathway (Wang and Struhl, 2004). Elegant studies done in flies to study the juxtacrine notch signaling pathway has shown that Epsin-dependent Delta endocytosis in the signal-sending cell is required for signaling (Wang and Struhl, 2004). Supporting evidence comes from Epsin-deficient mutants in flies, worms, and mice where defects in notch signaling pathway such as cardiovascular development, germline, and neural tube differentiation were observed (Tian *et al.*, 2004; Chen *et al.*, 2009).

Other Epsin-specific cargoes that undergo UIM-mediated internalization are the epithelial sodium channel ENaC (Wang *et al.*, 2006) and the Vascular Endothelial Growth Factor Receptor-2 (Tessneer *et al.*, 2013).

Progression from an initiated pit into a vesicle depends on reaching a critical mass of cargo and endocytic components. Epsin-1 contributes to this checkpoint which when unsatisfied will result in the destabilization and abortion of pits (Sen *et al.*, 2012). In addition to serving as an endocytic adaptor protein, Epsins are proposed to function as stabilizers of the endocytic network. Yeast Epsins have also shown to play an analogous role in expanding and sustaining the endocytic network by mediating protein–protein interaction via their NPFs and UIMs (Dores *et al.*, 2010).

The Epsin family of adaptor proteins has been recognized as regulators of cancer progression (Tessneer *et al.*, 2013). Epsins are upregulated in skin, breast, prostate, pancreatic, and lung cancers (Tessneer *et al.*, 2013; Sen *et al.*, 2012). The enhanced invasion potential of Epsin-overexpressing cells is attributed to the nonclassical Epsin function in RhoGTPase signaling regulation that leads to enhanced cell migration and invasion (Coon *et al.*, 2010). In addition, Epsin's role in angiogenesis by regulating VEGFR2 levels has been demonstrated, and considered as a potential treatment of cancer. Knockout of Epsin in Lewis Lung Cancer model effectively reduced tumorigenesis by misregulation of VEGFR2 and angiogenesis (Tessneer *et al.*, 2013).

The EpsinR Family

These adaptors bear an ENTH domain similar to Epsin (Figure 2), but differs in lipid specificity as it binds PI(4)P and

therefore, localizes to the TGN. EpsinR (epsin-related protein) has an AP1-binding motif [D/E]FxD[F/W] and four identified CBM of the consensus DΦF. Some of the cargo proteins under control of EpsinR include M6PR and the SNARE protein Vtib (Hirst *et al.*, 2004; Mills *et al.*, 2003). This adaptor is believed to play a role in cargo recycling to the TGN.

Eps15 Family

The presence of UIMs in Eps15 (Figure 2) indicates that, similar to Epsin, this protein is capable of ubiquitinated-cargo recognition (although lacks coat-binding determinants). Eps15 contains NPF-binding, EH domains in the N-terminus which also interacts with PI(3,5)P₂ (Naslavsky *et al.*, 2007). The Eps15 coiled-coiled region following the EH domain is involved in protein dimerization (van Bergen En Henegouwen, 2009) and along with the UIMs have been shown to define distinct cargo-specificity (c-MET and EGFR) (Parachoniak and Park, 2009; Sigismund *et al.*, 2005; De Melker *et al.*, 2004; Polo *et al.*, 2002). The C-terminus also houses an array of AP2-interacting motifs, and an AP1-interacting motif. Other members of this family include Eps15R which is structurally similar to Eps15 and Eps15b, but lacks the N-terminal EH-domains (van Bergen En Henegouwen, 2009).

In addition to its involvement in endocytosis, Eps15 co-operates with AP1 in sorting cargo at the Golgi apparatus. Indeed, mutation of the AP1 binding site on Eps15 impaired the secretion of nascent secretory proteins and TGN-to-endosomal transport of mannose-6-phosphate receptor (van Bergen En Henegouwen, 2009).

AP180 and Clathrin Assembly Lymphoid Myeloid Leukemia

The ubiquitous clathrin assembly lymphoid myeloid leukemia (CALM) protein and its neuronal counterpart the assembly protein 180 (AP180) have a characteristic ANTH (AP180 N-terminal homology) domain (structurally related to the ENTH domain) (Figure 2). AP180/CALM binds to PI(4,5)P₂, but does not induce membrane deformation (Stahelin *et al.*, 2003). The C-terminus of AP180/CALM has a subtype of CBMs (DL[L/F] – Aspartate, Leucine[Leucine/Phenylalanine]), and several NPF motifs. Except for the yeast homologs, AP180s contain multiple AP2-binding motifs. AP180s are found conserved in yeast (Yap1801, Yap1802), *Caenorhabditis elegans* (unc-11), and in *Drosophila melanogaster* (Lap) while CALM is only present in mammalian cells.

CALM and AP180 play a conserved role in the endocytosis of SNAREs, specifically vesicle-associated membrane proteins (VAMP)/ R-SNAREs (Moshkanbaryans *et al.*, 2014). Depletion of AP180 and CALM in hippocampal neurons resulted in aberrant retention of synaptobrevin2/VAMP at the neuronal surface, while the abundant synaptic vesicular protein vGLUT1 was unaffected. CALM also plays a role in VAMP3 and VAMP8 internalization in non-neuronal cells. Study of the CALM–SNARE interface by X-Ray crystallography revealed that the N-terminal half of the SNARE domain binds the ANTH

domain in a manner similar to the SNARE complex formation (Moshkanbaryans *et al.*, 2014).

The involvement of CALM and AP180 in neurodegenerative diseases has gained enormous support in recent years. Genome wide-association study identified alterations in the *PICALM* gene encoding CALM as a genetic risk factor in the onset of Alzheimer's disease (AD) (Moshkanbaryans *et al.*, 2014). It has also been implicated in affecting cognitive function with aging. A recent study directly correlated the levels of CALM to the levels of pathogenic Aβ complexes in AD, by affecting the endocytosis and localization of Aβ-secretase involved in the production of toxic Aβ (Kanatsu *et al.*, 2014). On the contrary, cytotoxicity of Aβ peptide was reduced in yeast, worms, and in mice cortical neurons by overexpressing AP180 family of proteins (Moshkanbaryans *et al.*, 2014). Although these studies are contradictory, they emphasize the role of CALM in APP processing highlighting its therapeutic potential for treatment of AD.

PTB Domain Containing Family (DAB, ARH, and Numb)

This family of adaptor proteins is comprised of neuronal disabled-1 (Dab1), ubiquitous Dab2, autosomal recessive hypercholesterolemia (ARH), and numb which share a common phosphotyrosine binding domain (PTB) (Figure 2). This fold is commonly found in signaling molecules and binds to phosphorylated-tyrosines. However, the PTB domain of this adaptor family specifically recognizes the tyrosine-based signal (FX)NPXY on the cytoplasmic tail of receptor proteins (Mishra *et al.*, 2002). The PTB domain structure has been solved and shows simultaneous binding of cargo and PI(4,5)P₂ (Dvir *et al.*, 2012; Stolt *et al.*, 2003) and hence regulates vesicle budding from the plasma membrane. These adaptors have been linked to CME via their interaction with AP2 and/or clathrin directly. Dab2 and ARH interact with AP2 and clathrin, while numb and Dab1 only interact with AP2. Additionally, Dab2 has multiple NPF motifs capable of binding to EH domain containing proteins such as Eps15 (Figure 2).

Dab2 and ARH have been reported to be functionally redundant for CME of LDLR (Keyel *et al.*, 2006; Maurer and Cooper, 2006). However, while ARH-mediated LDLR internalization required AP2, Dab2-mediated LDLR internalization does not (Keyel *et al.*, 2006; Maurer and Cooper, 2006). The AP2-binding mechanism is very distinct for ARH as it engages AP2 by binding the β2 appendage while the others bind to the α-appendage of AP2 (Mishra *et al.*, 2005).

Dab2 was also required for albumin internalization (Maurer and Cooper, 2005) by recognizing the (ΦX)NPXY motif on the cytoplasmic tail of the albumin receptor, megalin (Gallagher *et al.*, 2004). PTB domain containing adaptor proteins bind to the amyloid precursor protein family as a (YX)NPXY motif is conserved among members (Howell *et al.*, 1999; Homayouni *et al.*, 1999). Both numb and Dab2 have been implicated in the endocytosis of integrins which also contains NPXY motifs in their cytoplasmic tails (Bridgewater *et al.*, 2012).

Mutations in ARH lead to defective endocytosis of LDLR and in consequence to hypercholesterolemia. Dab2 is unable to compensate for the loss of ARH, due to the low levels of

expression of Dab2 in hepatocytes. The role of Dab and Numb in APP processing and production of $A\beta$ has been exploited and depletion of these adaptor proteins was shown to reduce the levels of $A\beta$ production (Xie *et al.*, 2012).

Arrestin Family

The arrestin family of adaptor proteins shares a common arrestin-fold domain and consists of α -arrestins, a group of vacuolar protein sorting (Vps) 26 related proteins, visual and nonvisual arrestins or β -arrestins. The members of this family show evolutionary conservation from humans, flies, and worms to yeasts (Aubry *et al.*, 2009). Arrestin family in humans has 14 members: 6 α -arrestins, 4 visual and β -arrestins, and 4 Vps26 genes. Phylogenetic analysis suggests that β -arrestins, the best-studied members of this clan, branched from the α -arrestins and coevolved with G-protein coupled receptors (GPCRs) to mediate their internalization (Alvarez, 2008). The Arrestins were named for their scaffolding function in binding and terminating G-protein coupled signaling. However, many more functions of this protein family in assisting the internalization of cargoes including GPCRs have been described since.

In addition to functioning in signaling regulation of GPCRs by binding to their cytoplasmic tails, β -arrestins' ability to act as adaptor proteins became clear as they can bind clathrin and AP2 via motifs in their C-termini (Owen *et al.*, 2004; Figure 2). Also, arrestin interaction with phosphoinositides at the plasma membrane is required for recruitment of the cargo into endocytic vesicles (Gaidarov *et al.*, 1999). Structural studies have shed light on the mechanism of action of β -arrestins. In an inactive phosphorylated state, intramolecular interactions between the N- and C-domains of arrestins lead to the shielding of a core of polar residues involved in the recognition of cargo and binding other elements of the endocytic machinery. Arrestin binding to an activated phosphorylated GPCR and subsequent arrestin dephosphorylation (by an unknown phosphatase) disrupts the intramolecular interactions in arrestins and allows binding to the endocytic machinery (Kang *et al.*, 2014).

Arrestins internalize cargoes from the plasma membrane and traffic them to the early endosomes by binding phosphorylated Ser/Thr clusters in their C-termini (Kang *et al.*, 2014). The rates of receptor recycling and degradation depend on the strength of receptor–arrestin interaction. For example, Class-A receptors (β 2 Adrenergic receptor, vasopressin 1a) with weak interaction are recycled back quickly, whereas Class-B receptors (angiotensin II type 1A receptor, vasopressin 2 receptor) with strong interaction are recycled slowly (Kang *et al.*, 2014). Arrestins get ubiquitinated by the E3 ubiquitin-ligase Mdm2 and their ability to recruit deubiquitinases (DUBs) and undergo deubiquitination also leads to differential consequences. While Class-A receptor–arrestin complex recruits DUBs leading to receptor recycling, Class-B receptors do not have a conformation that supports DUB recruitment and hence leads to stable ubiquitination and degradation (Kang *et al.*, 2014). Subsequently, arrestin–GPCR interaction strength also affects signaling. Specifically Class-B receptors result in the formation of stable signalosomes due to a strong interaction.

Opsin/rhodopsin family of GPCRs serve as cargoes for the visual arrestins. In addition to classic GPCRs, β -arrestins also interact with activated/phosphorylated unconventional GPCRs (Dishevelled and Smoothened), Receptor Tyrosine Kinases (IGF-1R, TGF β RIIR), and ion channels (NHE1/5, Ca(v)1, TRPV4, Nicotinic cholinergic receptor) to mediate their internalization.

The vps26-related proteins are structurally more similar to β -arrestins than to other members of the family. Vps26A/B, 29, and 35 are four mammalian members of the Vps family part of the so-called retromer complex. The retromer is involved in endosomes-to-TGN cargo transport. However, Vps26 is not directly involved in cargo recognition and therefore, cannot be considered an adaptor.

α -Arrestins lack the helix 1 that forms the polar core of inactive β -arrestins. Another major difference is that the C-terminus of α -arrestins contains PPXY motifs instead of the clathrin- and AP2-binding sites found in β -arrestins. Members of the α -arrestin family include the 10 yeast ARTS (Arrestin related trafficking adaptors) and the 6 α -arrestin (ARRDC 1–5; Arrestin domain containing proteins and TXNIP Thioredoxin-interacting protein) mammalian proteins.

ARTS in yeast have been shown to function as cargo adaptors for the HECT ubiquitin-ligase Rsp5, i.e., facilitating cargo ubiquitination and internalization (Lin *et al.*, 2008). Similar to ARTS in yeast, the role for ARRDCs in mammalian cells as E3 ligase adaptors has been well-established linking GPCR to E3 HECT ubiquitin ligases Nedd4, AIP4, WWP1, and WWP2. In addition, ARTS have been shown to function as secondary adaptors to recruit cargo, β -arrestin-E3 ligase complex on early endosomes (Nabhan *et al.*, 2010). Further, they interact with components of the ESCRT complex and hence are implicated in multivesicular body/vacuolar sorting.

GPCRs represent the largest family of receptors (~1000 members) that localize on the cell surface and serve as target for about 40% of the drugs available. Therefore, arrestins are considered valuable targets to control GPCR signaling regulation. Further, arrestin involvement in pathological conditions has been substantially documented. Mutation of visual arrestins is associated with blindness following photoreceptor death due to impaired receptor desensitization. An alternative mechanism leading to blindness by stable association of visual arrestin to the photoreceptor rhodopsin has been suggested (Chen *et al.*, 2006). Overexpression of β -arrestins in AD contributes to the formation of extracellular neuritic plaques containing the amyloid- β ($A\beta$) peptide. This key pathogenic component of AD was reduced by disrupting the interaction between β -arrestin and β 2-adrenergic receptor which in turn lowers $A\beta$ production (Jiang *et al.*, 2013). β -Arrestins participate in signaling pathways mediated by Smoothened and Frizzled are required for the maintenance and onset of chronic myeloid leukemia (CML). Recently, targeting β -arrestin by RNA-apamers was effective in reducing tumorigenic growth in CML models and patient samples (Kotula *et al.*, 2014).

The Adaptor Protein Network

As described above, adaptors bear multiple-binding motifs that mediate several types of protein–protein interactions. This

promiscuous binding behavior has two general consequences: (1) it allows low-affinity (micromolar range) protein–protein interactions to sustain stable, but dynamic, multi-protein structures, and (2) it confers these massive complexes with classical network properties. For example, it is clear that AP2 at the plasma membrane (or AP1 at the TGN/endosomal level) along with clathrin constitute the ‘hubs’ (maximal connectivity centers) of the adaptor network. This observation explains why these key components are regulatory targets allowing the fast assembly or disassembly of the adaptor network.

SNAREs: Membrane Fusion and Beyond

Introduction: A Brief Historical Perspective on Soluble *N*-Ethylmaleimide-Sensitive Factor Attachment Protein Receptors (SNAREs)

The genesis of the discovery of SNAREs and the molecular mechanisms of their mode of action have been recently covered in details in several reviews (Jahn and Scheller, 2006; Sotirakis and Galli, 2007; Hussain and Davanger, 2011; Mellman and Emr, 2013) including the press release of the 2013 Nobel Prize in Physiology and Medicine (Nobelprize.org, 2013). In brief, the initial SNARE hypothesis of membrane fusion was proposed in the seminal article by Rothman and coworkers (Söllner *et al.*, 1993). This hypothesis was based on their discovery of a complex composed of a synaptic vesicle protein (vesicle-associated membrane protein, VAMP2) and two plasma membrane proteins (Syntaxin 1 and SNAP-25), suggesting that this complex (named SNARE complex) allows vesicles to dock and fuse with their target membrane. The take-home message of 20 years of work on SNAREs, from 1993 to 2013, is certainly that SNAREs are both necessary and sufficient for membrane fusion. Their necessity was shown by genetic studies in several organisms (most notably amoebae, fly, worm, and mouse) which showed paralytic phenotype when VAMP1 or VAMP2 were inactivated (see Schoch *et al.*, 2001; Nystuen *et al.*, 2007 for mouse VAMP null mutants' phenotype) and the finding that clostridial neurotoxins, the most potent blockers of neurotransmitter release, a special case of vesicular traffic, are zinc-proteases which cleave and inactivate synaptic SNAREs (Galli and Haucke, 2004). The sufficiency of SNAREs for membrane fusion was essentially shown using artificial membranes devoid of any other protein (Weber *et al.*, 1998) and cells modified to express SNAREs on their surface (Hu *et al.*, 2003). In these systems, the formation of a complex between a vesicular SNARE (v-SNARE) on one membrane and its target SNARE (t-SNARE) on the other membrane was sufficient to drive the fusion of these membranes. Still the story of SNAREs was not fully written yet as much remained to be understood, notably on how SNAREs operate at the molecular level and how they organize intracellular membrane traffic both spatially and temporally. Here we will illustrate the current frontiers in 'SNARE science' with two main topics: (1) the biophysical properties of SNAREs as membrane fusion nanomachines and (2) their emergence as multitask proteins with a special focus on the case of the Longin SNARE proteins Sec22b and TI-VAMP/VAMP7.

SNAREs: Membrane Fusion Nanomachines

The first reconstitution of SNAREs in artificial membranes was carried out by the Rothman lab (Weber *et al.*, 1998). In this work, they generated a population of liposomes bearing the synaptic vesicle protein VAMP2 (v-liposomes) on one hand,

and another population of liposomes carrying the presynaptic plasma membrane t-SNARE composed of Syntaxin 1 and SNAP-25 (t-liposomes) on the other hand. *In vivo*, VAMP2 and Syntaxin 1 each contain a C-terminal transmembrane domain (TMD), whereas SNAP-25 lacks a TMD, and is targeted to the presynaptic plasma membrane *via* palmitoylation of its central cysteine residues. Here the trick consisted in using bacteria coproducing Syntaxin 1 and SNAP-25, thus generating high amounts of properly folded and active t-SNAREs. Fusion was measured using Förster resonance energy transfer (FRET) between two fluorochromes, NBD and rhodamine, linked to lipids of the v-liposome. Upon fusion with t-liposomes, the fluorescent lipids are diluted and the FRET signal decreases proportionally. While this initial reconstitution experiment supported the notion that SNAREs constitute the minimal machinery for membrane fusion, it could not tell how they operate. Membrane fusion is thermodynamically unfavorable mainly because repulsive forces between the hydration layers of two interacting membranes oppose their approach at distances less than ~ 2 nm. *In vitro*, close membrane apposition and fusion can be triggered artificially, in the absence of any proteins, upon the addition of divalent cations (Duzgunes *et al.*, 1981) or poly-ethylene glycol (Lentz, 2007). So how do SNAREs produce similar membrane-bridging effects? The crystal structure of the synaptic SNARE complex (Sutton *et al.*, 1998) revealed that an essential domain of the SNARE proteins, therefore referred to as the SNARE motif, was able to fold as a coiled-coil upon formation of the SNARE complex. In this structure, the SNARE motifs assemble as a four-helix bundle (VAMP2 and Syntaxin 1 each contribute one helix and SNAP-25 contributes two helices) with the four helices oriented in parallel (N-termini at the same end). Later studies then showed that v- and t-SNAREs assemble from their membrane-distal N-termini and toward their membrane-proximal C-termini, thus bringing the membranes close together as they fold-up (Melia *et al.*, 2002; Sorensen *et al.*, 2006; Figure 1).

The energy released during this zipper-like assembly was evaluated using a surface forces apparatus, which measures the interaction energy as a function of distance between two mica-supported lipid bilayers. In this experiment, one bilayer was functionalized with the cytoplasmic domain of VAMP2 (v-SNARE) and the other one with the cytoplasmic domain of Syntaxin 1 bound to SNAP-25 (t-SNARE); these v- and t-SNAREs were covalently attached to their respective bilayer through a lipidic anchor instead of their natural TMD. In this setup, v- and t-SNAREs started to assemble when the bilayers were ~ 10 nm apart and formed a partially zippered complex (unstructured in its membrane-proximal region) releasing ~ 35 k_BT (Li *et al.*, 2007), an amount of energy well compatible with the notion that SNAREs provide the energy for membrane fusion. Indeed, the energy required to fuse two lipid bilayers was estimated in the range of 50–100 k_BT (Cohen and Melikyan, 2004). Recent experiments at the single

Figure 1 Core mechanism of the SNARE fusion nanomachine. The transport vesicle (v-) SNARE protein (in blue) forms a membrane-bridging complex with the target membrane (t-) SNARE protein (in red). This complex assembles like a zipper (from the N-terminal toward the C-terminal regions of the cognate v- and t-SNARE proteins), which brings the membranes into close apposition and triggers their fusion. Munc18 (in orange, shown only on the left for clarity) acts as a stabilizer of the SNARE complex; its U-shape geometry is appropriate to clasp the four-helix bundle of zippering t- and v-SNARE proteins.

SNARE complex level using optical or magnetic tweezers (Gao *et al.*, 2012; Min *et al.*, 2013) have confirmed the energy released by partial (membrane-distal) assembly of the SNARE complex and further found the occurrence of sequential zippering intermediates, with full zippering releasing ~ 65 k_BT. This is particularly interesting because it suggests that SNARE complexes do not necessarily wind up completely leading to fusion at once and opens the possibility for regulation of C-terminal zippering (and thus membrane fusion) by regulatory proteins. Several groups have then studied the number of SNARE complexes required to fuse membranes. Whilst one seemed to be enough in the case of liposomes fusing *in vitro* (van den Bogaart *et al.*, 2010), two to three appeared to be required for the exocytosis of secretory vesicles *in vivo* (Hua and Scheller, 2001; Mohrmann *et al.*, 2010; Sinha *et al.*, 2011). These apparently contradictory results were recently reconciled using a novel lipid bilayer nanodiscs system, which showed that although one SNARE complex was enough to trigger lipid bilayer mixing, at least three SNARE complexes were necessary for efficient content mixing (Shi *et al.*, 2012). Whether or not SNARE complexes are arranged geometrically (Megighian *et al.*, 2013) potentially by partners like Sec1/Munc18 (SM) proteins or complexins (Rizo *et al.*, 2006; Kummel *et al.*, 2011) to provide the energy required for fusion synergistically still needs to be further studied. From this, we are led to conclude that SNAREs operate as a mechanical device delivering energy to the membranes to bring them in close proximity until they fuse.

This then raises the questions of how the force is transmitted to the interacting bilayers and what is the role of SNARE TMDs in this mechanism. These questions have been studied using both *in vitro* liposome fusion assays (McNew *et al.*, 1999, 2000) and *in vivo* electrophysiological recordings in chromaffin or neuronal cells (Kesavan *et al.*, 2007; Zhou *et al.*, 2013) by extending the region between the SNARE motifs and the TMDs and/or replacing the TMDs with lipidic anchors. Introducing a flexible linker of ~ 10 amino acids between the SNARE motif and the TMD of VAMP2 or Syntaxin 1 did not affect liposome fusion *in vitro* (McNew *et al.*, 1999) or spontaneous vesicle fusion *in vivo* (Kesavan *et al.*, 2007), but it severely impaired calcium-mediated neurotransmitter release *in vivo* (Kesavan *et al.*, 2007; Zhou *et al.*, 2013). Addition of longer (~ 20 amino acids) flexible linkers completely

abolished fusion both *in vitro* and *in vivo*. In addition, helical continuity between SNARE motifs and TMDs is not required for fusion as shown by the moderate effect on liposome fusion when introducing two prolines in the juxtamembrane domain of VAMP2 or Syntaxin 1 (McNew *et al.*, 1999). Altogether these results show that conformational coupling between SNARE assembly and the TMDs is not important for fusion *per se*, and suggest that the force for fusion is rather transmitted by pulling on the membrane anchors as SNARE motifs zipper their membrane-proximal end. This notion is further supported by experiments in which TMDs could be functionally replaced by lipidic anchors *in vitro*, as long as the hydrophobic chain of the lipid was long enough to span both leaflets of the bilayer (McNew *et al.*, 2000) and *in vivo*, where both VAMP2 and Syntaxin 1 anchored *via* 'short' lipids could replace the endogenous molecules (Zhou *et al.*, 2013). Functional restoration *in vivo* appeared nevertheless incomplete for evoked release which suggests that TMDs may be involved in coupling SNAREs with some other components involved in calcium-triggered fusion events. The fact that *in vitro* fusion requires long hydrophobic anchors, while *in vivo* fusion apparently does not, can be explained by the absence of accessory proteins in minimal reconstitution systems. The membrane buckling effect resulting from pulling on both leaflets of the bilayer at once upon zippering of cognate SNAREs – when they are anchored to long hydrophobic anchors *in vitro* (McNew *et al.*, 2000) – could be compensated *in vivo* by regulatory proteins with membrane deformation properties, such as synaptotagmin (McMahon *et al.*, 2010; Bharat *et al.*, 2014). This is consistent with *in vitro* reconstitution experiments of yeast vacuolar fusion (Xu *et al.*, 2011), where fusion by lipid-anchored SNAREs was only possible in the presence of accessory proteins involved in membrane tethering and protein recycling.

The Regulators of the SNARE Nanomachine

Another fundamental question in the field of intracellular membrane traffic is how SNARE assembly is regulated to allow fusion to occur at the right place and at the right time under the control of specific signaling mechanisms. We will here only briefly present the main proteins that collaborate with SNAREs

to regulate membrane fusion events spatially and temporally. Sec1/Munc18 (SM) proteins are probably the most important partners of SNAREs, which are now even considered (together with the 4 SNARE motifs) as the fifth component of the core membrane fusion nanomachine (Sudhof and Rothman, 2009). Accordingly, *in vivo* deletion of SM proteins leads to a severe reduction of neurotransmission in various organisms including flies, nematodes and mice (Harrison *et al.*, 1994; Verhage *et al.*, 2000; Weimer *et al.*, 2003). The structure of SM proteins displays a U-shaped geometry, with the central cavity being involved in SNARE binding (Archbold *et al.*, 2014). The neuronal SM protein Munc18-1 binds to the closed (fusion incompetent conformation) of the Syntaxin 1 molecule (Misura *et al.*, 2000), but also to the SNARE complex (with Syntaxin 1 in its open conformation) (Dulubova *et al.*, 2007). The first mode of binding may protect Syntaxin 1 from undesirable interactions during its trafficking toward the plasma membrane, whereas the second mode of binding may stabilize SNARE complex and thus stimulate fusion. *In vitro*, the synaptic SM protein Munc18-1 was shown to exclusively activate membrane adhesion and fusion mediated by the synaptic SNARE complex, thus improving fusion specificity (Tareste *et al.*, 2008; Shen *et al.*, 2007). Interestingly, another *in vitro* reconstitution experiment has demonstrated that the HOPS complex (a multicomponent tethering complex of the endolysosomal system including the SM protein Vps33) protects membrane-bridging SNARE complexes from being disassembled by the Sec17p/Sec18p recycling machinery (Xu *et al.*, 2010). A conserved feature of the SM proteins thus seems to be their ability to clasp the four-helix bundle of zippering SNARE complexes, thus increasing their assembling energy (Figure 1).

Proteins from the complexin and synaptotagmin families constitute another class of SNARE regulators that are particularly important in calcium-triggered fusion events. These regulators are not necessary for fusion *per se* (Geppert *et al.*, 1994; Reim *et al.*, 2001), but they allow the accumulation, at the plasma membrane, of a pool of fusion-ready vesicles awaiting the signal (calcium entry) for rapid and synchronous release. Recent genetic and biophysical studies indicate that complexin traps the SNARE complex in a partially zippered, fusion incompetent state, and that calcium-bound synaptotagmin releases this clamp probably by physically displacing

complexin from the SNARE complex (Tang *et al.*, 2006; Schaub *et al.*, 2006; Giraudo *et al.*, 2006). Complexin exerts its clamping activity by binding to the membrane-proximal region of the t-SNARE, thus preventing its assembly with the C-terminal residues of the v-SNARE (Giraudo *et al.*, 2009; Li *et al.*, 2011). In addition to releasing the complexin clamp and thus allowing full SNARE complex zippering, calcium-bound synaptotagmin might activate fusion upon its insertion into the plasma membrane, which induces positive (fusion-promoting) curvature (McMahon *et al.*, 2010; Figure 2).

In conclusion, SNAREs appear as the basic nanomachine for intracellular membrane fusion in vesicular traffic and they operate most likely by mediating close apposition of membranes, which lowers the energy barrier for fusion. How exactly SNARE assembly is coupled to membrane fusion and what is the role of SNARE TMDs in the process still need to be clarified. The mechanics of the SNARE nanomachine is regulated by proteins from the SM, complexin, and synaptotagmin families, which facilitate or inhibit SNARE assembly to allow precise spatial and temporal organization of membrane fusion events.

SNAREs: More than Fusogenic Proteins? The Case of the Longin v-SNAREs Sec22b and TI-VAMP/VAMP7

After the discovery that SNAREs constitute the core machinery of membrane fusion, several studies have suggested that SNAREs could play additional functions linked to their interactions with other proteins involved in membrane traffic. Here we will review the particular case of the Longin v-SNAREs Sec22b, found to be involved in membrane contact sites and TI-VAMP/VAMP7, which we propose to view as a multitask protein.

Our recent data suggest a role for Sec22b in neurite growth through anchoring the endoplasmic reticulum (ER) to the plasma membrane, and generating a non-fusogenic SNARE complex involved in plasma membrane growth (Petkovic *et al.*, 2014). The role of the ER in plasma membrane expansion is well-established, because it is the major site of lipid synthesis in cells, and the source of secretory vesicles which are required for growth. Recent studies have also highlighted roles for membrane contacts between the ER and other organelles

Figure 2 Model for complexin and synaptotagmin function in calcium-triggered fusion. Before calcium entry, complexin (in purple) clamps fusion by binding to the C-terminal region of the t-SNARE protein, thus preventing full assembly of the SNARE complex. This clamp is further stabilized by synaptotagmin (in green), which also binds to SNAREs in the absence of calcium. Upon calcium entry, synaptotagmin modifies its mode of binding to SNAREs, which displaces complexin and induces C-terminal assembly of the SNARE complex. Concomitantly, calcium-bound synaptotagmin inserts into the plasma membrane thus causing positive (fusion-promoting) curvature. Munc18 was removed from this scheme to better illustrate the role of complexin and synaptotagmin.

including the plasma membrane. ER-plasma membrane contact sites (MCS) are thought to be involved in (1) the exchange of molecules, such as lipids, between the two bilayers, (2) the function of ER-localized enzymes that act 'in trans' on the plasma membrane, and (3) the control of calcium homeostasis (Toulmay and Prinz, 2011; Stefan *et al.*, 2011; Hogan *et al.*, 2010; Friedman and Voeltz, 2011; Elbaz and Schuldiner, 2011). In cells of higher eukaryotes, MCS were first described by electron microscopy in the 1950s in the case of muscle cells (Porter and Palade, 1957), where they are extremely abundant and are responsible for depolarization-contraction coupling. MCS are also abundant in neurons (Rosenbluth, 1962) and have subsequently been described in many other cell types. Yeast cells are particularly rich in MCS, where approximately half of the ER localizes to the cell periphery. There are an estimated 1100 sites per yeast cell in which the distance between the ER and the plasma membrane is less than 30 nm (Pichler *et al.*, 2001). Mutants in six genes involved in MCS also lead to growth defects in yeast (Manford *et al.*, 2012), suggesting a clear link between MCS and growth. We found that the ER-localized v-SNARE Sec22b interacts with the plasma membrane t-SNARE Syntaxin 1 in neurons, and experiments in budding yeast also showed an interaction between Sec22 and the plasma membrane t-SNARE Sso1 (ortholog of Syntaxin 1), suggesting conservation of the interaction. We did not find co-immunoprecipitation of Sec22b with SNAP-23, -25 or -29, suggesting that Sec22b is not part of a fusogenic SNARE complex at ER-plasma membrane contact sites. Accordingly, the complex Syntaxin 1/Sec22b did not mediate fusion either in neurons *in vivo* or between liposomes *in vitro* (Petkovic *et al.*, 2014). Interestingly, a similar binary Syntaxin 4/Sec22b (without SNAP-23) complex was identified in mammalian dendritic cells (Cebrian *et al.*, 2011). Introduction of a long rigid spacer between the SNARE and the TMDs, increasing the distance between ER and plasma membrane, impaired neuronal growth but did not perturb the role of Sec22b in the secretory pathway. We further demonstrated that elimination of Sec22 function in yeast impaired the non-vesicular lipid transfer of phosphoinositides between the ER and the plasma membrane, and that Sec22 and Sso1 interact with Osh2 and Osh3, two lipid transfer proteins (LTPs). Interestingly, extended-Synaptotagmin 2 (E-Syt2), a protein closely related to the neuronal synaptotagmin partners of the synaptic SNARE complex, and which regulates the formation of ER-plasma membrane contact sites (Giordano *et al.*, 2013), was recently suggested to be a phospholipid transfer protein (Schauder *et al.*, 2014). Together, these results lead us to propose that the interaction between ER Sec22 and plasma membrane Syntaxin participates in MCS function (Figure 3), likely fostering non-vesicular lipid transfer by shortening the distance between the membranes, and that this highly conserved mechanism contributes to plasma membrane expansion (Petkovic *et al.*, 2014). While most ER-plasma membrane contact sites are 30 nm large, the Sec22b/Syntaxin 1 complex could possibly bring them as close as 10 nm (Figure 3). Interestingly, in yeast, Sec22 interacts with Sso1 and the SNAP25-like Sec9, and is involved in the transport of the autophagy-related protein Atg9 (Nair *et al.*, 2011), suggesting that Sec22b and Syntaxin 1 could coordinate lipid transfer when SNAP-25 is kept out of their complex (by an as yet

Figure 3 Putative role of Sec22 and Syntaxin at ER-plasma membrane contact sites. A complex of Sec22 and Syntaxin is shown to tether in close proximity the endoplasmic reticulum membrane and the plasma membrane and to interact with lipid transfer proteins (in yellow), as shown for oxysterol-binding protein Osh2/3 in yeast. Extended-synaptotagmin 2 (E-Syt2) is an ER protein which is involved in membrane contact sites and could potentially also interact with the non-fusogenic binary Syntaxin/Sec22 SNARE complex depicted. Other tethering factors (such as STIM1-Orai1) are depicted without detail.

unidentified mechanism/factor), and classical membrane fusion regulating autophagosome biogenesis when SNAP-25 or possibly another SNAP is present.

Our team has identified and characterized TI-VAMP/VAMP7, a SNARE protein localized to secretory vesicles and insensitive to tetanus and botulinum neurotoxins (Galli *et al.*, 1998). VAMP7 has the classical SNARE sequence with a SNARE motif and a TMD but also includes an N-terminal extension which we called Longin domain (Filippini *et al.*, 2001). The Longin domain plays an auto-inhibitory role through intramolecular interaction with the SNARE motif thus controlling the fusogenic activity of VAMP7 (Martinez-Arca *et al.*, 2000, 2003). We have characterized the role of VAMP7 and searched for its partners by yeast two-hybrid screens, an approach which proved to be very productive in that case. Screens performed with the cytoplasmic domain of VAMP7 as bait pulled out its already known SNARE partners: Syntaxin 1, Syntaxin 3, SNAP-23 and SNAP-25 (Burgo *et al.*, 2009; Martinez-Arca *et al.*, 2003; Figure 4). These molecules are present at the plasma membrane and the SNARE complexes VAMP7/Syntaxin 1/SNAP25 and VAMP7/Syntaxin 3/SNAP-23 are thought to allow for fusion of secretory vesicles with the plasma membrane (Chaineau *et al.*, 2009).

We further identified the interaction of VAMP7 with the δ -subunit of the molecular coat AP-3 in yeast two-hybrid screens using its Longin and cytoplasmic domains as baits in both fly and human libraries (Burgo *et al.*, 2009; Formstecher *et al.*, 2005; Martinez-Arca *et al.*, 2003; Figure 4). AP-3 is a clathrin adaptor involved in the intracellular targeting from the Golgi apparatus and endosomes, to lysosomes and secretory organelles, including secretory lysosome-related organelles and synaptic vesicles. Mutations in AP-3 subunits lead to coat dilution, bleeding, and neurological defects (Kantheti *et al.*, 1998). Recent work further suggests important function of AP-3 in the biogenesis of peptide-secreting granules at the Golgi apparatus (Sirkis *et al.*, 2013; Asensio *et al.*, 2010).

Figure 4 VAMP7 network of protein–protein interactions. Direct partners of VAMP7 include the neuronal t-SNAREs Syntaxin 1 and SNAP-25, the non-neuronal t-SNAREs Syntaxin 3 and SNAP-23, all involved in exocytosis, Hrb involved in clathrin-dependent endocytosis, AP-3 involved in sorting to late endosomes and synaptic vesicles, and Varp. Varp is a guanine-nucleotide exchange factor of Rab21. Varp interacts with the molecular motor Kif5A and GolginA4. One of Rab21's effectors is MACF1 a very large protein which binds to both actin and microtubules. GolginA4 interacts also with MACF1. In summary, VAMP7 network of interaction includes proteins involved in the three major vesicular trafficking processes: sorting, transport, and fusion. The present interactome is not exhaustive and solely illustrates the above-mentioned principle.

Accordingly, the VAMP7/AP-3 interaction was further found to be crucial for intracellular targeting of VAMP7 to late endosomes in non-neuronal cells and synaptic vesicles in neurons (Bennett *et al.*, 2008; Proux-Gillardeaux *et al.*, 2007; Salazar *et al.*, 2006; Martinez-Arca *et al.*, 2003). This interaction was then confirmed at the structural level and was shown to involve Longin residues interacting with the SNARE motif (Kent *et al.*, 2012). Whether VAMP7 is sorted *in solo* by AP-3 as originally suggested by the interaction with both Longin and cytoplasmic domains (Martinez-Arca *et al.*, 2003) or in complexes with t-SNAREs (Kent *et al.*, 2012) is not yet clear.

Another partner identified in yeast two-hybrid screens using the cytoplasmic domain of VAMP7 as bait was HIV Rev binding protein (Hrb) (Pryor *et al.*, 2008; Chaîneau *et al.*, 2008; Figure 4). We showed that Hrb, which is a clathrin accessory protein (Schmid and McMahon, 2007), is involved in clathrin-dependent endocytosis (Chaîneau *et al.*, 2008) in good agreement with the phenotype of the Hrb knockout mouse (Khawaja *et al.*, 2010) demonstrating that Hrb loss leads to inefficient transferrin uptake, a typical clathrin-dependent mechanism, and in contrast with the proposal of a role of Hrb restricted to VAMP7 clathrin-dependent endocytosis (Pryor *et al.*, 2008).

We then went on to show that VAMP7 interacts with Vps9 and Ankyrin repeat protein (Varp) (Burgo *et al.*, 2009), an exchange factor for the small GTPase Rab21 (Zhang *et al.*, 2006; Figure 4) and effector of Rab32/38 (Wang *et al.*, 2008). Varp interacts with the closed conformation of VAMP7 (Schafer *et al.*, 2012). More recently, again using yeast two-hybrid screens with Varp and Rab21 as baits, we showed that VAMP7 is the starting point of a molecular network that combines proteins belonging to the main classes involved in vesicular trafficking (Figure 4): Varp, kinesin 1 (Kif5A), a

molecular motor partner of Varp, GolginA4, a Golgi attachment factor partner of Varp, and the spectraplakine MACF1, an effector of Rab21 (Burgo *et al.*, 2012), which binds both actin and microtubules. We found that this network can send VAMP7 vesicles to the cell periphery along microtubules, thus allowing exocytosis.

In conclusion, these studies altogether show that VAMP7, on top of its SNARE fusogenic activities with several t-SNAREs, is also able to interact with molecules involved in sorting (AP-3 and Hrb) and transport (the Varp-Kif5A-GolginA4-Rab21-MACF1 molecular network) (Figure 4). Whether VAMP7 plays an active role in recruiting AP-3, Hrb and Varp or is just a follower remains to be determined as we do not know if there are any defects of AP-3, Hrb and/or Varp function in the absence of VAMP7. The idea that SNAREs are more than mere fusogenic proteins but are also connected with proteins involved in sorting has also been illustrated for VAMP2 which interacts with AP180 and Calm, both involved in clathrin-dependent endocytosis (Miller *et al.*, 2011; Koo *et al.*, 2011) and for VAMP4 which interacts with AP-1, involved in clathrin-dependent sorting at the *trans*-Golgi network (Hinnens *et al.*, 2003; Peden *et al.*, 2001). This would further suggest that sorting, fusion, and possibly transport are closely connected at the molecular level.

Conclusion

In conclusion, 20 years of work on SNAREs have convincingly led to the principle that they constitute the core nanomachines for intracellular membrane fusion. SNAREs also form non-fusogenic complexes playing a role in the generation of membrane contact sites, and interact with multiple proteins

involved in sorting and transport, thus making them emerge as general organizers of intracellular membrane adhesion and fusion events.

History

Proteins that comprise the endosomal sorting complexes required for transport (ESCRT) machinery were identified in screens for vacuolar protein sorting (vps) mutants in the yeast *Saccharomyces cerevisiae* that share a common 'class E phenotype' in which newly synthesized vacuolar proteins as well as recycled Golgi components accumulate in a prominent 'class E compartment' built of stacked cisternae adjacent to an otherwise normal yeast vacuole (Raymond *et al.*, 1992). Endocytosed plasma membrane proteins also concentrate in this class E compartment (Davis *et al.*, 1993), identifying it as a central sorting station 'en route' to the vacuole. Additional studies demonstrated that class E gene function is required to deliver transmembrane cargo into the endosomal interior (Odorizzi *et al.*, 1998), connecting the class E compartment and failed multivesicular body (MVB) biogenesis.

Molecular analysis of class E gene products identified Vps4 as an AAA + ATPase (Babst *et al.*, 1997) that controls cycling of other class E proteins on and off the endosomal membrane (Babst *et al.*, 1998). Studies in the early 2000s established that most of the remaining class E gene products form heterooligomeric complexes that were named endosomal sorting complexes required for transport (ESCRTs), including ESCRT-0 (Bilodeau *et al.*, 2002; Katzmann *et al.*, 2003), ESCRT-I (Katzmann *et al.*, 2001), ESCRT-II (Babst *et al.*, 2002a), and ESCRT-III (Babst *et al.*, 2002b). ESCRT complexes and Vps4 are conserved across evolution (Babst, 2005; Leung *et al.*, 2008) and a large body of literature now supports a broad and general role for this machinery in endolysosomal sorting and function.

The discovery that ESCRTs play an essential role in the life cycle of the human immunodeficiency virus (HIV-1) and related retroviruses by enabling release from infected cells solidified the idea that ESCRTs are centrally involved in membrane scission when vesicles (or viruses) bud away from the cytoplasm (Garrus *et al.*, 2001). The finding that ESCRTs participate in cytokinesis and cell division even in Archaeobacteria that lack internal membranes lent additional support to this concept (Carlton and Martin-Serrano, 2007; Morita *et al.*, 2007; Samson *et al.*, 2008; Lindas *et al.*, 2008) and also suggested that cell division might be the primordial function of the ESCRT machinery. Successful reconstitution of ESCRT-driven vesicle formation in giant unilamellar vesicles in 2010 solidified a broad and still current framework for understanding ESCRT function (Wollert *et al.*, 2009a; Wollert and Hurley, 2010).

While the intervening years have seen advances in structural and functional analyses of the ESCRT machinery in many contexts and pathways, fundamental questions remain about how components of the ESCRT machinery – and especially ESCRT-III and Vps4 – operate to drive membrane scission. Models abound, but definitive answers await new approaches and systems. Recent excitement in the field comes from

expanded appreciation of non-endosomal roles for components of the ESCRT machinery. These support an emerging concept of ESCRT complexes as modular machinery that functions to remodel cellular membranes (Figure 1) in cooperation with other factors highlighted elsewhere in this volume.

ESCRT Machinery

ESCRT proteins and the complexes they form are soluble and associate transiently with membranes, similar to other membrane trafficking and remodeling factors. In their best known role – delivering cargo protein into the vacuole or lysosome – ESCRT complexes can be divided into those that cooperatively bind ubiquitin, phosphatidylinositol 3-phosphate, and each other to recruit cargo and initiate membrane deformation and vesicle formation on the endosomal membrane (ESCRT-0, -I, and -II) and those that complete the release of vesicles into the MVB (ESCRT-III and Vps4). The numbering of the ESCRT complexes is based on the order in which they are recruited for vacuolar protein sorting in yeast although, as will be apparent in the following discussion, these are modular complexes that function in different combinations depending on the system involved. A brief description of ESCRT complexes follows, and their protein components in well-studied model organisms are shown in Table 1. Excellent in-depth reviews discussing ESCRT complex structure and organization can be found in (Hurley, 2010; Henne *et al.*, 2011; Wollert *et al.*, 2009b; Hanson and Cashikar, 2012).

Early Acting ESCRTs

ESCRT complexes implicated in cargo recognition and early stages of intraluminal vesicle (ILV) formation include ESCRT-0 (composed of Vps27/Hrs and Hse1/STAM), ESCRT-I (composed of Vps23/Tsg101, Vps28, Mvb12, and Vps37), and ESCRT-II (composed of Vps36/EAP45, Snf8/EAP30, and Vps25/EAP20). Each of these complexes is a constitutive heterooligomeric complex and depletion of any single subunit destabilizes the whole complex. Important features of these early acting complexes include a number of low-affinity ubiquitin-binding motifs for cargo recognition (all three), phosphatidylinositol 3-phosphate-binding sites for endosomal targeting (ESCRT-0 and ESCRT-II), and specific motifs that connect the complexes to each other and in the case of ESCRT-II to ESCRT-III. Other factors able to engage and activate ESCRT-III can replace some or all of these early acting ESCRT complexes, expanding the repertoire of molecular pathways into the MVB. The best studied of these are Bro1-domain containing proteins such as Alix that (like the early acting ESCRT complexes) bind both ubiquitin and CHMP4 family ESCRT-III proteins (Katoh *et al.*, 2003; Dowlatshahi *et al.*, 2012; Pashkova *et al.*, 2013).

Figure 1 Sites of ESCRT function around the cell. Schematic drawing that highlights the many places around the cell where ESCRT machinery is thought to function. Red dots represent the ESCRT machinery. Well-studied roles in multivesicular body (MVB) biogenesis and virus budding are shown in detail, and highlight the unique role of this machinery in budding events directed away from the cytoplasm. Once formed, MVBs fuse with lysosomes for degradation and with the plasma membrane to release exosomes. At the midbody, ESCRTs separate dividing cells. Not shown is a comparable role in severing neurites during neuronal development. At the cell surface, ESCRTs organize signaling platforms for pH sensing and resolve membrane lesions (indicated by a lightning bolt). At the nuclear envelope, ESCRTs are implicated in nuclear pore complex quality control. Finally, ESCRTs are present in cilia, where details of their function have yet to be uncovered.

ESCRT-III and Vps4

ESCRT-III and its AAA ATPase Vps4 are the central players in ESCRT-driven membrane scission. The overall structure of individual ESCRT-III proteins (Muziol *et al.*, 2006; Bajorek *et al.*, 2009; Xiao *et al.*, 2009) and the filamentous assemblies they form (Hanson *et al.*, 2008; Cashikar *et al.*, 2014; Henne *et al.*, 2012) is established (Figure 2). A number of models describing how rings and spirals on the membrane might facilitate membrane remodeling and scission have been proposed and are discussed further below. There are 7 non-redundant ESCRT-III or ESCRT-III related proteins in the yeast *S. cerevisiae* and 12 in humans, and a varying but generally similar complement in other eukaryotes. All are predicted to share a core molecular structure in which a helical hairpin is surrounded and regulated by short C-terminal helices (Muziol

et al., 2006; Bajorek *et al.*, 2009). ESCRT-III proteins cycle between a closed or autoinhibited conformation in the cytoplasm and an open or activated conformation on the membrane that is primed for polymer assembly (Lin *et al.*, 2005; Zamborlini *et al.*, 2006; Shim *et al.*, 2007). ESCRT-II and Alix bind ESCRT-III proteins to initiate ESCRT-III polymer assembly. ESCRT-III then grows in a process for which mechanisms controlling composition and final size have yet to be defined. Assembled ESCRT-III polymers are intrinsically stable but because of Vps4-driven disassembly are short-lived in the cell (Cashikar *et al.*, 2014; Babst *et al.*, 2002b). Studies using RNAi to examine roles for individual ESCRT-III proteins support a general conclusion that particular ESCRT-III proteins are more or less essential in different settings. A general requirement for one protein related to Snf7/CHMP4 and one related to Vps2/CHMP2 appears to be conserved in most

membrane remodeling processes (Hanson *et al.*, 2009). The reader is referred to original descriptions of ESCRT-III polymers cited above and previous reviews (McCullough *et al.*, 2013; Peel *et al.*, 2011; Henne *et al.*, 2013) for additional details.

ESCRTs and Other Cellular Machinery

In addition to the interactions that connect ESCRT complexes to each other and to cargo, there are a wide range of other factors that bind to different ESCRT proteins. A list compiled in 2010 identified 31 interactors for ESCRT-0 components, 25 for ESCRT-I, 6 for ESCRT-II, and 12 for ESCRT-III (Roxrud *et al.*, 2010), and many more have emerged since that time. Interesting examples include connections between Hrs in ESCRT-0 and clathrin or retromer that are important for controlling entry into the degradative pathway (Raiborg *et al.*, 2002; Strohlic *et al.*, 2008), potential regulators of ESCRT-III assembly (CC2D1A is proposed to regulate incorporation of CHMP4 into ESCRT-III (Martinelli *et al.*, 2012)), and connections to the cytoskeleton (RILP bridges ESCRT-II to dynein, promoting late endosomal transport (Wang and Hong, 2006; Progida *et al.*, 2007)). Surveys of known and suspected protein–protein interactions involving ESCRTs suggest that many functional partners are waiting in the wings for analysis as insight into ESCRT function expands.

Models of ESCRT Function

ESCRT complexes are modular but interconnected entities that most clearly act at the MVB to recognize and concentrate cargo, facilitate membrane deformation to initiate vesicle formation, and finally constrict vesicle necks to drive membrane scission. The modular nature of the ESCRT machinery provides flexibility in how their function can be harnessed to accomplish a range of activities. Models for how ESCRTs operate in MVB biogenesis as well as the topologically related processes of viral particle release and cytokinesis are explored in a number of reviews written over the past few years (Hurley and Hanson, 2010; McCullough *et al.*, 2013; Hanson and Cashikar, 2012; Henne *et al.*, 2013).

Common to all ESCRT-dependent reactions is the need for membrane scission, and despite general agreement that ESCRT-III filaments are centrally involved much remains to be learned about how they actually facilitate this critical endpoint for ESCRT pathway function. Current thinking centers on ways in which ESCRT-III filaments with their known propensity to spiral inside membrane tubes or necks of varying diameter could promote membrane scission, either on their own or with assistance from the disassembling ATPase Vps4. Most models build on the general idea that ESCRT-III spirals create a dome that promotes scission when the attached membrane is drawn into a sufficiently narrow neck (Fabrikant *et al.*, 2009). Variations on this invoke a more dynamic role for ESCRT-III

Figure 2 ESCRT-III filament spirals. Deep-etch electron micrograph showing endogenous ESCRT-III filament spirals on the plasma membrane of a HeLa cell treated with siRNA to deplete Vps4a and Vps4b. Scale bar represents 100 nm.

filaments in neck constriction and membrane scission, often in conjunction with Vps4. Dome-based models of membrane scission are supported by computational analyses confirming energetic plausibility (Fabrikant *et al.*, 2009; Elia *et al.*, 2012), but many aspects remain difficult to conceptualize and new approaches with greater spatial and temporal resolution are needed to clarify the driving principles responsible for this reaction and its regulation.

ESCRTs in the Endolysosomal System

ESCRTs are responsible for delivering membrane and membrane proteins into the endosomal interior for degradation in the lysosome or vacuole. This broad and essential role places them at the heart of the endolysosomal pathway, with control over the fate of membrane proteins that enter the endosomal system. Comprehensive insight into which ESCRTs are required for ILV biogenesis is available in *S. cerevisiae*, where mutation of components across the entire pathway including ESCRT-0, ESCRT-I, ESCRT-II, four 'core' ESCRT-III proteins, and Vps4 all lead to formation of multilamellar class E compartments that lack ILVs (Raymond *et al.*, 1992; Nickerson *et al.*, 2006). Importantly, temperature sensitive class E mutant strains reform ILVs upon return to permissive temperature (Russell *et al.*, 2012).

Ubiquitination is both necessary and sufficient for entry of membrane proteins into the MVB (Piper *et al.*, 2014) and is the trigger for initiating recruitment of ESCRTs to create an ILV.

In the typical pathway, ESCRT-0 is the first point of contact and in turn facilitates sequential engagement of downstream ESCRT complexes. A key transition point occurs upon recruitment of the Snf7 component of ESCRT-III. Mutations 'upstream' of Snf7 (in components of ESCRT-0, -I, and -II as well as Vps20) lead to enhanced recycling of proteins to the cell surface while mutations downstream of Snf7 do not (Teis *et al.*, 2010). This observation supports a working model in which upstream ESCRT complexes are important for collecting and concentrating ubiquitinated cargo that is then encircled by ESCRT-III filament(s) prior to release into the endosomal interior on an ILV.

A large body of work in other systems supports the general concept that the ESCRT machinery is essential for efficiently delivering membrane proteins to the lysosome for degradation (Rusten *et al.*, 2012). ESCRT mutations typically result in enlarged endosomes that contain few or no ILVs and do not successfully sort and degrade membrane proteins, including a wide variety of signaling receptors that then accumulate on endosomal membranes and continue to signal. One or another ESCRT component has been shown to be essential for downregulating receptor tyrosine kinases such as the epidermal growth factor receptor, a number of G protein coupled receptors, Wnt receptors, integrins, transforming growth factor beta (TGF- β) receptors, and more. Other membrane proteins such as gap junctions similarly depend on the ESCRT machinery for degradation (Leithe *et al.*, 2009). Interestingly, mutation or inactivation of individual ESCRT components is typically not lethal at the cellular level but leads instead to varying phenotypes that can usually be ascribed to dysregulated signaling. These can have dramatic effects at the organismal level, and in many cases are lethal during development. Overall, while it is clear that ESCRT function is key in the endosomal system, the complexity of phenotypes arising from perturbations in what is clearly an intricate and multistep set of events has made a full understanding of the ESCRT pathway and its connections with other machinery in the endolysosomal system challenging. There is clearly much yet to be learned.

ESCRTs in Virus Budding

HIV was the first virus shown to usurp the ESCRT machinery for budding and release from the plasma membrane of infected host cells (Garrus *et al.*, 2001; Martin-Serrano *et al.*, 2001; VerPlank *et al.*, 2001) in what has emerged as a general mechanism underlying release of most membrane-enclosed viruses (Votteler and Sundquist, 2013). In the case of HIV, the virally encoded Gag protein assembles on the plasma membrane to sequester the viral genome into an incomplete spherical particle. Viral Gag proteins use well-defined 'late domain' motifs to engage the ESCRTs and thereby release the virus. In the case of HIV Gag there are two late domain motifs, PT/SAP and LYPX_nL, that bind specific domains of Tsg101 (ESCRT-I) (Garrus *et al.*, 2001; Martin-Serrano *et al.*, 2001; VerPlank *et al.*, 2001) and Alix (Strack *et al.*, 2003), respectively. Different retroviruses use one or the other of these connections to the ESCRT machinery (Votteler and Sundquist, 2013) to directly or indirectly engage ESCRT-III and Vps4

(Baumgartel *et al.*, 2011; Jouvenet *et al.*, 2011). As in the case of ILV biogenesis, the prevailing view is that ESCRT-III filaments spiral on the cytosolic side of a narrowing neck to drive membrane scission (Bleck *et al.*, 2014; Ladinsky *et al.*, 2014; Cashikar *et al.*, 2014; Peel *et al.*, 2011; McCullough *et al.*, 2013). Other ideas including a proposal that ESCRT-III might instead assemble and act from within the viral particle (Van Engelenburg *et al.*, 2014) are also being considered. Open questions about the relationship between ESCRT-III, Vps4, and viral structural proteins such as HIV Gag include: (1) how is the extent of Gag assembly coordinated with ESCRT engagement to produce viral particles with an appropriate but incomplete (Carlson *et al.*, 2008) Gag shell?, (2) what molecule(s) connects Gag to ESCRT-III and how are these connections controlled?, (3) what role does Vps4 play and does it act at one, two, or more stages?, and finally (4) how do ESCRT-III filament spirals promote membrane scission?

ESCRTs in Cytokinesis

An evolutionarily ancient role of the ESCRT machinery is in cytokinesis. In organisms ranging from Archaea to mammalian cells, ESCRTs are important for successful abscission at the end of cytokinesis. Perhaps the clearest demonstration that their function is required is in certain Archaeobacteria that lack the typical fission-promoting GTPase FtsZ and instead use a cell division (cdv) system consisting of two ESCRT-III proteins and Vps4 (Bernander and Ettema, 2010). In the context of a multicellular organism, a recent study demonstrates that cytokinetic abscission during female germline stem cell division in *Drosophila* requires ESCRT proteins Shrub and Alix (Eikenes *et al.*, 2015).

In cultured mammalian cells where involvement of ESCRTs in cytokinesis has been most thoroughly explored, comprehensive siRNA screens defined the subset of ESCRT proteins required for successful cell division (Morita *et al.*, 2010; Carlton and Martin-Serrano, 2007). Interestingly, these include ESCRT-I, a subset of ESCRT-III and cooperating factors including Vps4 but not ESCRT-0 or ESCRT-II. This parallels requirements for virus release (Morita *et al.*, 2011) and may define a common set of scission promoting factors. Live cell imaging of fluorescently tagged proteins demonstrated that the centrosomal protein CEP55 arrives at the midbody early in cytokinesis and then recruits ALIX and ESCRT-I followed by two bursts of ESCRT-III (Elia *et al.*, 2011; Guizetti *et al.*, 2011). One proposal is that ESCRT-III filaments help to constrict the intercellular bridge by virtue of their decreasing spiral diameter and tight association with the membrane (Elia *et al.*, 2012). Vps4 may facilitate this reaction by freeing a sub-pool of ESCRT-III to generate an abscission-promoting spiral (Elia *et al.*, 2011). Many aspects of this process need further clarification, including the significance and function of ESCRT-III at two sites, the relationship between ~17 nm filaments seen by thin section electron microscopy (EM; Guizetti *et al.*, 2011) and ESCRT-III or other cytoskeletal components, the relative timing and role(s) of spastin versus Vps4 (Guizetti and Gerlich, 2012), and finally the role of additional proteins implicated in cytokinesis including MITD1, Brox, and others.

Recently described regulatory control of ESCRT-III ensures that abscission is delayed until chromatin segregation is complete. Termed the abscission checkpoint (NoCut), Aurora B kinase phosphorylates CHMP4C to delay abscission when chromatin lags within the intercellular bridge (Carlton *et al.*, 2012). Another protein, ANCHR (abscission/NoCut checkpoint regulator, previously known as ZFYVE19), also participates in this pathway, trapping Vps4 at the midbody together with CHMP4C in cells that contain chromatin bridges (Thoresen *et al.*, 2014). ANCHR may thus separate Vps4 from ESCRT-III in order to delay abscission. These studies provide strong support for the central role of the ESCRT machinery in cytokinesis.

ESCRTs in Extracellular Vesicle Biogenesis

Aside from delivery to lysosomes, MVBs can also fuse with the plasma membrane to release their contents from the cell. This phenomenon was first observed by EM in studies of transferrin receptor trafficking in maturing reticulocytes (Harding *et al.*, 1983). Vesicles released into the cell culture medium were termed 'exosomes' (Pan and Johnstone, 1983). Virtually all cells are now thought to produce exosomes, and these vesicles comprise one class of the broad collective of extracellular vesicles (EVs) (Raposo and Stoorvogel, 2013). An increasing body of evidence points to the ubiquity of EV release and implicates EVs as signaling units capable of eliciting phenotypic responses in cells with which they come into contact, as discussed elsewhere in this volume.

MVBs thus have two potential fates: degradation or secretion. While degradation predominates in most situations, it is not known what controls the fate of individual MVBs. Furthermore, MVB fate may change in response to cellular or environmental cues. There are indications that heterogeneity among MVBs may correlate with their eventual fate; for example, lysobisphosphatidic acid is concentrated in ILVs targeted for degradation (Matsuo *et al.*, 2004) but is largely absent from exosomes (Kowal *et al.*, 2014; Trajkovic *et al.*, 2008). Regulated recruitment of exocytosis-enabling Rab GTPases such as Rab27a (Ostrowski *et al.*, 2010), Rab35 (Hsu *et al.*, 2010), or Rab11 (Savina *et al.*, 2002) and their effectors is likely to be one factor correlated with secretion.

How involved the ESCRT machinery is in exosome (and more broadly EV) biogenesis is still an open question.

Because of the topology of EV formation (budding away from the cytoplasm), an early and logical hypothesis was that EV formation would utilize the same machinery responsible for creating ILVs within MVBs 'en route' to degradation, i.e., the ESCRTs. Proteomic studies abound in EV research, and many such studies identify ESCRT proteins as components of the EV proteome (Simpson *et al.*, 2009; Choi *et al.*, 2013). In fact, Tsg101 (ESCRT-I) and Alix are among the most common markers used to identify EVs (Kowal *et al.*, 2014). Despite interest in the role of the ESCRT machinery in EV biogenesis, it has remained unclear if ESCRT function is generally required for EV biogenesis. Seemingly straightforward experimental tests in different systems provide contradictory results (Trajkovic *et al.*, 2008; van Niel *et al.*, 2011; Baietti *et al.*, 2012; Colombo *et al.*, 2013) leading to the idea that at least some

EVs may be created without the help of ESCRTs (Babst, 2011; Buschow *et al.*, 2009). However, while lipids clearly affect EV biogenesis (Trajkovic *et al.*, 2008), ESCRT-independent pathways for controlling EV formation have not emerged. In fact, proteins recently implicated in EV biogenesis have each revealed new connections to the ESCRT machinery. In one example, the adaptor protein syntenin-1 binds syndecans and other transmembrane proteins and promotes their release in exosomes by recruiting Alix and ESCRT-III (Baietti *et al.*, 2012; Hurley and Odorizzi, 2012). In another example, the arrestin domain protein ARRDC1 interacts with Tsg101 and ubiquitinated proteins at the plasma membrane to stimulate EV formation and release (Nabhan *et al.*, 2012). A number of reports indicate that perturbing ESCRT function can affect EV number, content, or size (Colombo *et al.*, 2013; Baietti *et al.*, 2012). EM of artificial immunologic synapses showed that dominant-negative Vps4 inhibits release of ectosomes at the plasma membrane (Choudhuri *et al.*, 2014). Our finding that ESCRT spirals accumulate on the plasma membrane in Vps4 depleted cells suggests the possibility of similar release from other cultured cells (Cashikar *et al.*, 2014). Further understanding of how the ESCRT machinery contributes to generating EVs will aid in developing tools to manipulate EV biogenesis.

Non-Endosomal Roles for the ESCRT Machinery

It has been clear for some time that ESCRTs have non-endosomal roles that extend beyond viral budding and cytokinesis. Functions ranging from cell cycle control to gene silencing to cell polarity were highlighted in a 2006 review of the ESCRT machinery (Slagsvold *et al.*, 2006), but because the underlying mechanisms were not defined, these observations did not change the consensus view that ESCRTs operate primarily to drive membrane budding and scission at the MVB. Findings over the past few years highlighting a new set of non-endosomal functions for the ESCRTs – discussed below – are likely to rejuvenate interest in a broader consideration of ESCRT function throughout the cell.

pH Sensing

Sensing and responding to the surrounding environment is an ancient requirement for cell survival. A prime example is the conserved and well-studied alkaline pH-sensing pathway in fungi, which is important for both viability and virulence (Peñalva *et al.*, 2008; Davis, 2009). A receptor at the cell surface senses alkaline extracellular pH (Negrete-Urtasun *et al.*, 1999; Herranz *et al.*, 2005) and induces proteolytic activation of a transcription factor, which in turn increases expression of genes important for maintaining the proton gradient, promoting nutrient absorption and iron homeostasis (Davis, 2009; Peñalva *et al.*, 2008). Mutational analyses established the necessity of ESCRTs for pathway activation (Calcagno-Pizarelli *et al.*, 2011). Early efforts to connect ESCRT function in pH sensing to the endosomal network have given way to experiments demonstrating that ESCRTs operate at the plasma membrane in this pathway. Imaging studies show that ESCRTs localize to the cell cortex, rather than endosomes, for function

in pH sensing (Galindo *et al.*, 2007, 2012). One proposal is that ESCRTs function in pH signaling by corraling signaling components at the plasma membrane to bring the responsible calpain protease into contact with its substrate to release the activating transcription factor (Peñalva *et al.*, 2014). This highlights what may be a general role for membrane-associated ESCRT-III filaments in creating functional domains along the membrane.

Plasma Membrane Resealing

All cells possess mechanisms to defend against loss of plasma membrane integrity. Plasma membrane repair is triggered by Ca^{2+} influx (Idone *et al.*, 2008) and has been connected with lysosomal exocytosis (Reddy *et al.*, 2001), endocytosis of damaged domains (Corrotte *et al.*, 2012), and most recently ESCRT-III mediated repair potentially via shedding of damaged membrane from the cell surface (Jimenez *et al.*, 2014). This novel role for ESCRTs emerged from the observation that Alix and ESCRT-III (but not ESCRT-0, -I, or -II) are recruited to lesions generated by exposing cells to detergent, pore forming toxins, or laser ablation (Jimenez *et al.*, 2014). Experiments using RNAi to deplete ESCRT-III proteins further demonstrated that these are required for cell viability after damage (Jimenez *et al.*, 2014). This process is modeled to involve the shedding of membrane vesicles from the cell surface (Jimenez *et al.*, 2014). Direct constriction by spiraling ESCRT-III filaments could also drive resealing (Andrews *et al.*, 2014).

Neurite Severing in Neuronal Development

A recent report establishes that ESCRTs mediate membrane scission during developmental pruning of axons and dendrites in *Drosophila* (Loncle *et al.*, 2015). As in cytokinesis, a subset of ESCRT proteins is required near the site of scission, in this case for efficient pruning or severing of dendrites. Critical among the required ESCRT proteins are *Drosophila* Snf7/CHMP4 (known as shrub) and its interacting Bro1-domain protein myopic (HDPTP in humans). The reaction appears to parallel that of abscission.

Activity at the Nuclear Envelope

Perhaps the least expected non-endosomal role for ESCRTs emerged last year with the description of a new and surprising role for ESCRT-III at the nuclear envelope in yeast. Mutational analyses revealed genetic interactions between genes involved in nuclear pore complex (NPC) assembly and a subset of ESCRTs (Webster *et al.*, 2014). Inactivating ESCRTs caused incomplete NPC clusters to accumulate and led to the idea that ESCRTs function in removing misassembled NPC oligomers. The lack of genetic interactions between NPC genes and those encoding ESCRT-0, -I, -II indicate that these complexes are not involved. The ESCRT-III protein Snf7 binds directly to Heh2 (related to emerin) at the inner nuclear membrane providing insight into how ESCRT-III may be recruited. However, how ESCRT-III detects malformed NPCs is unknown. Intriguingly, genetic analyses of spindle pole body duplication in *Schizosaccharomyces pombe* (but not *S. cerevisiae*)

defined a clear role for Vps4, Vps32, and Vps24 in this nuclear envelope-based event (Frost *et al.*, 2012) further highlighting potential roles for ESCRT-III at the nuclear envelope.

Organization and Membrane Dynamics in Cilia

Primary cilia are sophisticated sensory structures that project from the plasma membrane to mediate a variety of signaling functions including mechanosensation, osmosensation, and many developmental signaling events. Studies over past decade have uncovered cytoskeletal and trafficking pathways responsible for biogenesis and maintenance of the primary cilium, and ESCRT proteins have emerged as candidates involved in different aspects of ciliary function. Cilia are microtubule-based projections present in at least a single copy on most human cells (Satir *et al.*, 2010). Cilia are conserved throughout evolution including in single-celled organisms such as the green algae *Chlamydomonas reinhardtii* that possess a single flagellar cilium (Kim and Dynlacht, 2013). Assembly and turnover of cilia is frequently studied in *Chlamydomonas* (Kim and Dynlacht, 2013). Disassembly of cilia during cell division requires vesicular encapsulation of the ciliary transition zone, a structure that regulates protein import and export into and from the cilium (Cavalier-Smith, 1974; Diener *et al.*, 2015). ESCRTs, Vps4, and Alix were recently identified in proteomic studies of purified transition zones (Diener *et al.*, 2015). This raises interesting questions about how ESCRT might function at this specialized compartment. Both functional and imaging studies of ESCRT during the course of the cilium life cycle will be important to answering these exciting new questions.

Summary and Perspectives

The combination of increasingly incisive experiments designed to explore the mechanisms by which the ESCRT machinery promotes membrane remodeling and the emergence of new roles for the ESCRTs all around the cell promises that the next several years will see continued growth and excitement in the study of this fascinating and elaborate machinery.

The Retromer Complex

MNJ Seaman, University of Cambridge, Cambridge, UK

Introduction

Endosomes serve as a point of convergence between the secretory and endocytic pathways and as such operate to sort membrane proteins (often referred to as cargo) to three distinct destinations. A cargo protein in an endosome can be sorted for retrieval to the Golgi, recycling to the cell surface or delivered to a lysosome for degradation. Sophisticated sorting mechanisms therefore exist to ensure cargo proteins reach their correct destination (Seaman, 2008). A key element of the endosomal sorting machinery is the retromer complex. The retromer complex is ubiquitously conserved in eukaryotes and functions to sort cargo, tubulate membranes and also recruits various accessory proteins to endosomes that contribute to endosomal protein sorting and provide regulation of retromer. Aberrant endosomal protein sorting and dysregulation of the retromer complex is linked to many pathological processes including neurodegenerative diseases such as Alzheimer disease and Parkinson's disease and retromer function has been linked bacterial and viral pathogenesis. In this article the molecular cell biology of the retromer complex and its function in endosomal protein sorting will be discussed.

A Brief History of Retromer

The mechanisms that govern sorting and delivery to the vacuole in yeast are very similar to the sorting and trafficking of lysosomal hydrolase receptors such as the cation-independent mannose 6-phosphate receptor (CIMPR) in mammals and other metazoan eukaryotes and hence yeast makes an excellent model system. The retromer complex was first identified in the yeast *Saccharomyces cerevisiae* through the analysis of vacuolar protein sorting (VPS) mutants. Genetic screens for *vps* mutants in yeast identified approximately 40 genes that are required for the efficient delivery of the yeast vacuolar hydrolase, carboxypeptidase Y (CPY) to the vacuole (reviewed in Bowers and Stevens, 2005). A key protein required for sorting CPY to the vacuole is a type-I membrane protein encoded by the *VPS10* gene (Marcusson *et al.*, 1994). The Vps10 protein is a receptor that binds to CPY in the late-Golgi and is concentrated into clathrin-coated vesicles which are then delivered to a prevacuolar endosome (Deloche *et al.*, 2001). The dissociation of CPY from Vps10p is induced by the luminal environment in the endosome, CPY then proceeds to the vacuole whilst Vps10p is recycled back to the late-Golgi.

Analysis of *vps* mutants that exhibit similar vacuolar protease sorting phenotypes to the *vps10* mutant revealed the requirement for Vps35p, Vps29p, and Vps30p in mediating the retrieval of the Vps10 protein from endosomes to the Golgi (Seaman *et al.*, 1997). Biochemical experiments using chemical crosslinking agents subsequently demonstrated that Vps35p and Vps29p form a complex that also contains Vps26p, Vps5p, and Vps17p – the complex was called retromer

to denote its role in retrieval from endosomes (Seaman *et al.*, 1998).

The biochemical analysis of yeast retromer showed that the pentameric complex could be dissected into two distinct subcomplexes; a trimer of Vps35p, Vps29p, and Vps26p that was proposed to sort cargo; and a dimer of the Vps5 and Vps17 proteins that could assemble into large complexes and was suggested to fulfill a structural role of deforming the endosomal membrane to produce a vesicle or tubule. The Vps5 and Vps17 proteins are members of the sorting nexin (SNX) family and both contain a phox homology (PX) domain that binds to phosphatidylinositol 3-phosphate (PtdIns 3P) (Horazdovsky *et al.*, 1997; Yu and Lemmon, 2001). Although *vps30* mutants are phenotypically similar to *vps29* and *vps35* mutants, the Vps30 protein was not detected as part of the retromer complex and was later shown to regulate the retromer complex by modulating the activity of Vps34p, a phosphatidylinositol kinase that generates PtdIns 3P on endosomal membranes. This is discussed in detail later.

The Assembly and Structure of Retromer

Subsequent to the identification of retromer in yeast, much has been learned about how the trimer of the VPS35, VPS29, and VPS26 proteins assembles to create the cargo-selective complex. The crystal structures of VPS26 and VPS29 have been solved, the latter whilst bound to VPS35. The VPS26 protein is an arrangement of two domains comprising only β -sheets that together create a structure that is similar to arrestins (Shi *et al.*, 2006; Collins *et al.*, 2008). As arrestins have been shown to be able to interact with membrane proteins, in particular G-protein coupled receptors (GPCRs) (see Kang *et al.*, 2014 for review) to mediate their endocytosis, the structural similarity between VPS26 and the arrestin proteins hints that VPS26 may also be able to directly interact with cargo proteins.

The VPS29 protein is a mixture of α -helices and β -sheets that fold to form a globular protein that is structurally similar to the PPP family of protein phosphatases but VPS29 does not appear to exhibit phosphatase activity (Collins *et al.*, 2005; Swarbrick *et al.*, 2011). In contrast to VPS26 and VPS29, the structure of full length VPS35 has not yet been determined but it is believed that VPS35 forms a flexible rod-like structure made up of multiple helical repeats (Hierro *et al.*, 2007). Studies in mammalian cells using siRNA to silence expression of individual components of the retromer cargo-selective complex has shown that loss of one subunit leads to the instability and degradation of the other proteins (Arighi *et al.*, 2004; Seaman, 2004).

The N-terminal region of VPS35 binds to VPS26, an association that involves a conserved motif in VPS35 comprising Pro-Arg-Leu-Tyr-Leu (PRLYL) residues where mutation of the first leucine to proline abolishes the interaction (Haft *et al.*, 2000; Gokool *et al.*, 2007a). The importance of these residues

was discovered by analysis of a yeast mutant of Vps35p that exerts a dominant negative effect on Vps10p retrieval (Seaman *et al.*, 1998). The VPS35-VPS26 interaction is high affinity with a dissociation constant (K_D) of 4 nM (Collins *et al.*, 2008; Norwood *et al.*, 2011).

The VPS29 protein binds to the C-terminal region of VPS35 which forms a horse shoe-shaped arrangement of helices around the globular VPS29 protein (Hiero *et al.*, 2007). On the surface of VPS29 there are two conserved hydrophobic patches which lie on opposing faces. The patch that contains Val and Ile at positions 90 and 91 respectively is required for binding to VPS35 (Collins *et al.*, 2005). Mutation of Val90 to Asp or Ile91 to Ser respectively weakens or abolishes the VPS29-VPS35 interaction. The other conserved hydrophobic patch on VPS29 faces away from the VPS35-VPS29 interface and has been shown to be important for binding to the SNX proteins Vps5p and Vps17p in yeast but in mammalian cells other proteins bind at this site that regulate retromer function and these will be discussed later.

Within the horse shoe-shaped fold of VPS35, a key His residue at position 675 is required for binding to VPS29 forming a hydrogen bond with the Ile91 residue of VPS29 (Helfer *et al.*, 2013). The VPS35-VPS29 interaction is substantially weaker than the VPS35-VPS26 with a K_D of approximately 250 nM (Swarbrick *et al.*, 2011). With VPS26 and VPS29 respectively binding at the N- and C-termini of VPS35, the retromer cargo-selective complex is similar to a dumbbell where the central region is flexible possibly so that VPS26 and VPS29 are able to move relative to each other on mobile and dynamic endosomal membranes. This intrinsic flexibility of VPS35 may be an important aspect of the function of the retromer cargo-selective complex in selecting cargo proteins for trafficking out of endosomes.

The initial identification of retromer in yeast indicated that the complex is a relatively stable heteropentamer, albeit one with the property that it could be biochemically split into two distinct subcomplexes (Seaman *et al.*, 1998). In higher eukaryotes such as mammals, however, it appears that the retromer cargo-selective complex and SNX dimer associate only transiently (Seaman *et al.*, 2009; Harbour *et al.*, 2010; Swarbrick *et al.*, 2011). Why this should be is not clear although it has been suggested that evolutionary variation of the VPS29 protein which has resulted in yeast Vps29p containing sequences not present in other eukaryotes may determine the degree to which the retromer cargo-selective complex associates with the SNX dimer or other proteins that regulate retromer function and are not conserved in yeast (Harbour and Seaman, 2011) – these retromer accessory proteins are discussed later.

The SNX dimer functions to tubulate the endosomal membrane to generate the transport intermediates required for endosome-to-Golgi retrieval (Carlton *et al.*, 2004). The production of tubules from endosomal membranes by the SNX dimer is driven by the Bin-Amphiphysin-Rvs (BAR) domains in the C-terminal regions of the SNXs along with an intrinsic self-assembly activity (Peter *et al.*, 2004). The BAR domains comprise predicted coiled-coils regions that form homo- or heterodimers. In yeast Vps5p and Vps17p heterodimerise via their respective coiled-coil C-termini (Seaman and Williams, 2002) and in higher eukaryotes a similar arrangement exists. For example, in humans there are two Vps5p homologs, SNX1

and SNX2 and there are two orthologs of Vps17p, SNX5 and SNX6. Thus the retromer SNX dimer in humans is a heterodimer of SNX1 or SNX2 with SNX5 or SNX6 (Wassmer *et al.*, 2007).

The BAR domains adopt a curved banana-shaped structure that can self-assemble to drive membrane tubulation (Peter *et al.*, 2004). Not all members of the SNX family have BAR domains and therefore the SNX proteins with BAR domains are distinguished from the others by being described as SNX-BAR proteins (for review see van Weering *et al.*, 2010). Even among the SNX-BAR proteins there is much variation regarding the ability of individual BAR domains to form tubules – variation that stems from the presence of amphipathic sequences in certain BAR domains that promote tubule formation. For example, the BAR domains of SNX1 and SNX2 can readily promote tubule formation whilst recombinant SNX5 or SNX6 BAR domains do not exhibit this property (van Weering *et al.*, 2012). The interactions and assembly of the retromer proteins to form the cargo-selective complex and SNX dimer is shown schematically in Figure 1.

How Membrane Tubules are Stabilized

The tubules observed in mammalian cells that are positive for SNX1 are often several microns long. Maintaining a long membrane tubule over this distance will present a biological challenge, for without some form of stabilization or scaffolding a tubule will tend to break apart into vesicles. Fortunately the interaction of the retromer SNX dimer with the microtubule cytoskeleton can provide the means to attach the membrane tubule to a large scaffold such as a microtubule. The SNX5 and SNX6 proteins can bind to the p150glued protein (also known as dynactin) thereby linking the SNX dimer to microtubules and dynein-mediated movement along microtubules (Wassmer *et al.*, 2009). As dynein is a minus-end directed motor that will travel along microtubules toward the microtubule organizing center (MTOC), a structure that is located close to the Golgi complex, it is perfectly suited to linking with retromer and thereby participating in the endosome-to-Golgi pathway. Yeast do not appear to employ microtubules for membrane trafficking pathways and there is no evidence that either Vps5p or Vps17p can link to the microtubule cytoskeleton. Possibly the small size of yeast negate the requirement for the membrane tubules to be stabilized by the cytoskeleton as is required in much larger cells such as mammalian cells.

In higher eukaryotes such as mammals additional machinery appears to also be required for stabilizing the tubules formed by the retromer SNX dimer. It has been shown that the Eps15-homology domain protein-1 (EHD1) is required to stabilize tubules generated by SNX1 (Gokool *et al.*, 2007b). Interestingly, however, EHD1 does not appear to associate with SNXs but rather can interact with the retromer cargo-selective complex (Zhang *et al.*, 2012). The EHD family of proteins can assemble to form ring-like structures around membrane tubules in-vitro and, through an intrinsic ATP-hydrolyzing ability, may generate force to induce membrane tubule scission or else could operate as an additional scaffold to stabilize membrane tubules (Daumke *et al.*, 2007). The

Figure 1 Key elements of the retromer complex. (a) The VPS35, VPS29 and VPS26 assemble into a trimer that can bind to membrane proteins (cargo) and hence is known as the retromer cargo-selective complex. The structures of VPS26 and VPS29 have been solved and are shown in blue and green, respectively, and are based on the pdb entries 2R51 and 1Z2X (<http://www.rcsb.org/pdb/home/home.do>). (b) The C-terminal region of VPS35 forms a horse shoe-shaped fold around VPS29. Residues critical for the VPS35-VPS29 interaction, (e.g., VPS35 His675 and VPS29 Ile91) are located in the cleft between the two molecules. The structure shown is based on pdb entry 2R17. (c) The sorting nexin dimer associates with the membrane by binding to PtdIns 3P and can tubulate membranes through the action of the C-terminal BAR domains. The structure shown is pdb entry 4FZS.

precise details of how EHD proteins contribute to the endosome-to-Golgi pathway have yet to be determined.

Recruitment of Retromer

Before retromer can sort cargo or tubulate the membrane it must be recruited to the endosome. For the SNX dimer the process of membrane recruitment is mediated by the production of PtdIns 3P on the endosome by a PtdIns 3-kinase (Cozier *et al.*, 2002). In yeast the activity of the PtdIns 3-kinase is itself regulated by the Vps30 protein which forms a complex with Vps38 (Burda *et al.*, 2002). In higher eukaryotes the Vps30 homologue is known as Beclin and also acts to promote production of PtdIns 3P (Kihara *et al.*, 2001). This lipid is specifically enriched on endosomal membranes and the PX domains present within the SNXs bind to this lipid (Cheever *et al.*, 2001). The presence of PtdIns 3P is regulated not only by the kinase, but also by phosphatases of the myotubularin family (Cao *et al.*, 2008). Additionally, PtdIns 3P can be converted to PtdIns 3,5P₂ by the PIKFyve protein, another PtdIns kinase. As the SNXs bind PtdIns 3,5P₂ with generally lower affinity than PtdIns 3P this restricts the amount of PtdIns 3P available for binding by SNXs (Rutherford *et al.*, 2006). These mechanisms can provide spatial and temporal control of the amount of PtdIns 3P on endosomes and thereby regulate the membrane association of the SNX proteins.

For the retromer cargo-selective complex, endosomal membrane recruitment occurs by mechanisms distinct from

the SNXs. None of the retromer cargo-selective complex proteins can bind lipids directly and therefore recruitment is instead mediated by binding to proteins. In mammalian cells the small GTPase Rab7a plays a key role in regulating retromer cargo-selective complex recruitment and the association with Rab7a is conserved across many eukaryotes (Rojas *et al.*, 2008; Seaman *et al.*, 2009). In addition to Rab7a, the SNX SNX3 is also required (Harterink *et al.*, 2011; Vardarajan *et al.*, 2012). Unlike most SNX proteins, the SNX3 protein comprises a PX domain but little else and has been shown to bind to PtdIns 3P with high affinity (Yu and Lemmon, 2001). Using recombinant proteins it has been recently demonstrated that Rab7a and SNX3 together promote the membrane association of the retromer cargo-selective complex by binding to the VPS35 protein within the N-terminal region of VPS35 that also binds to VPS26 (Harrison *et al.*, 2014).

The requirement for both Rab7a and SNX3 to mediate the recruitment of the retromer cargo-selective complex may define the region of the endocytic system where retromer operates, namely, a point where Rab7a and SNX3 are sufficiently enriched to enable recruitment of the retromer cargo-selective complex. The typical punctate co-localization of GFP-tagged SNX3 and the retromer VPS26 protein is shown in Figure 2. Interestingly a mutation in Rab7a that causes Charcot-Marie-Tooth (CMT) disease, a peripheral neuropathy, reduces the binding of Rab7a to the retromer cargo-selective complex although it is not yet known how this contributes to the pathology of CMT disease (Seaman *et al.*, 2009; Harrison *et al.*,

Figure 2 Typical localization of the retromer cargo-selective complex. HeLa cells stably transfected with GFP-SNX3 were fixed and stained with monoclonal anti-GFP and polyclonal anti-VPS26 along with appropriate fluorescently labeled secondary antibodies. The proteins colocalise on numerous punctate structures that exhibit typical endosomal morphology and distribution. Scale bar = 20 μ m.

2014). The role of SNX3 in promoting the recruitment of the retromer cargo-selective complex, although potentially conserved in yeast where SNX3 is known as Grd19p and functions with retromer (Strochlic *et al.*, 2007), is not universal as plants do not appear to express a SNX3 homologue.

Recognition of Cargo

The role of SNX3 in retromer-mediated endosomal protein sorting goes beyond recruiting the cargo-selective complex to the membrane. Studies, initially conducted in yeast, have shown that SNX3 can also interact directly with membrane proteins ('cargo') that traffic in a retromer-dependent manner. In yeast, SNX3/Grd19p is required for the sorting of the Ftr1 protein, a protein required for iron homeostasis (Strochlic *et al.*, 2007), and dipeptidyl aminopeptidase A (DPAPA), a late-Golgi protease involved in the processing of the yeast mating pheromone, α -factor (Nothwehr *et al.*, 1996). Other studies conducted in yeast have shown that Vps35p interacts with the cytoplasmic tail of the CPY receptor, Vps10p (Nothwehr *et al.*, 2000). The finding that Vps35p can directly interact with cargo proteins was replicated for mammalian VPS35 and the cation-independent mannose 6-phosphate receptor (CIMPR) using the yeast two-hybrid system to investigate the interaction (Arighi *et al.*, 2004). Loss of retromer function in mammalian cells results in mislocalization and degradation of the CIMPR and the secretion of immature precursor forms of lysosomal hydrolases such as cathepsin D (Arighi *et al.*, 2004; Seaman, 2004).

Another cargo protein for retromer in mammalian cells is the iron transporter SLC11a2, also known as DMT1-II and Nramp2 (Tabuchi *et al.*, 2010) – mirroring the role of retromer in sorting the iron transporter protein, Ftr1p, in yeast. Studies conducted *in vitro* were able to demonstrate direct binding of the retromer cargo-selective complex to the C-terminal cytoplasmic domain of SLC11a2 through a hydrophobic motif, YLL (Tyr-Leu-Leu). This sequence is similar to motifs identified in the cytoplasmic tails of the CIMPR and sortilin, a mammalian homologue of the yeast Vps10 protein – WLM (Trp-Leu-Met) for CIMPR and FLV (Phe-Leu-Val) for sortilin (Seaman, 2007) – suggesting that retromer-mediated sorting

operates through a motif with a consensus of aromatic-Leu-hydrophobic. In worms and flies, developmental cues controlled by Wnt signaling require the action of the Wntless protein which is a cargo for retromer that also contains a hydrophobic aromatic-containing sequence in its cytoplasmic domain (Eaton, 2008).

Whilst the experimental evidence shows that VPS35 can bind to retromer cargo proteins, it is not the only component that can interact with cargo. The VPS26 protein can also bind to cargo proteins and has been shown to recognize the cytoplasmic tail of the SorL1 protein (also known as SorLA) (Fjorback *et al.*, 2012), a transmembrane protein that, like sortilin, is related to yeast Vps10p. The VPS26-SorL1 interaction is mediated by the motif FANSHY, (Phe-Ala-Asn-Ser-His-Tyr) in the SorL1 cytoplasmic tail. Presently, however, the precise molecular details of how VPS35 or VPS26 bind to cargo proteins remains to be determined but an interaction between VPS26 and cargo is consistent with structural similarities with arrestin proteins described previously. Some of the best characterized retromer cargo proteins are listed in Table 1.

Accessory Proteins that Modulate Retromer Function

Since its discovery in yeast and characterization in mammalian cells, a number of accessory proteins that associate with retromer to modulate its activity have been identified. In many cases there is a link to neurodegenerative disease through the accessory proteins that interact with retromer. The interaction of the SNX dimer with p150glued and the association of the retromer cargo-selective complex with EHD1 have been described previously as has the interaction of the retromer cargo-selective complex with Rab7a and SNX3.

The immunoprecipitation of tagged versions of the retromer cargo-selective complex has led to the identification of additional accessory proteins that modulate retromer activity and contribute to efficient endosomal protein sorting. The TBC1D5 protein associates with the retromer cargo-selective complex by binding to VPS29 (Seaman *et al.*, 2009; Harbour *et al.*, 2010). Interestingly, TBC1D5 binds to a hydrophobic patch on VPS29 that, in yeast, mediates the interaction between the retromer cargo-selective complex and the SNX dimer (Collins *et al.*,

Table 1 Notable cargo proteins that require retromer for their localization

Cargo protein	Function	Physiological process	Organism	Reference(s)
Vps10p	Vacuole hydrolase sorting	Vacuole biogenesis	Yeast	Seaman <i>et al.</i> (1997, 1998); Nothwehr <i>et al.</i> (2000)

2005). TBC1D5 is a member of the TBC family of proteins that regulate rab GTPases by promoting the hydrolysis of GTP by the respective rab and as such are referred to as rab GTPase activating proteins (GAPs) (see Fukuda, 2011 for review). An obvious potential target for TBC1D5 is the Rab7a protein that the retromer cargo-selective complex requires for its membrane association and indeed the nematode homologue of TBC1D5, the Rbg-3 protein, does promote hydrolysis of GTP by Rab7 (Mukhopadhyay *et al.*, 2007). In mammalian cells, overexpression of TBC1D5 causes the retromer cargo-selective complex to dissociate from endosomal membranes similar to the siRNA knockdown of Rab7a (Seaman *et al.*, 2009). Mutation of conserved Arg and Glu residues in the TBC domain of TBC1D5 that, based on the structure of TBC domains (Pan *et al.*, 2006), are predicted to be required for GAP activity renders TBC1D5 inactive with respect to affecting the membrane association of the retromer cargo-selective complex. Thus, TBC1D5 acts to control the membrane association of the retromer cargo-selective complex by regulating the activity of Rab7a.

Curiously, the retromer cargo-selective complex has recently been shown to associate with a protein called VARP that functions as a guanine nucleotide exchange factor (GEF) for Rab21 and an effector of Rab32/38 – Rab GTPases that are respectively linked with endosome-to-cell surface transport and melanosome biogenesis. What is intriguing about the retromer-VARP interaction is that it occurs through the same hydrophobic patch on VPS29 responsible for binding TBC1D5 (Hesketh *et al.*, 2014). Thus the association of the retromer cargo-selective complex with either VARP or TBC1D5 may provide the means for retromer to regulate sorting into multiple pathways leading away from endosomes.

Along with TBC1D5 and VARP, the retromer cargo-selective complex also interacts with the WASH complex (Harbour *et al.*, 2010) which functions to promote formation of branched actin patches on endosomes by activating the Arp2/3 complex. The WASH complex comprises five proteins; WASH1, KIAA1033, strumpellin, CCDC53, and FAM21 that form a stable complex (Derivery *et al.*, 2009). The strumpellin and KIAA1033 subunits of the WASH complex have respectively been linked with hereditary spastic paraplegia (HSP) and autosomal recessive intellectual disability (ARID) indicating

that WASH complex function is especially important in neuronal tissue (Valdmanis *et al.*, 2007; Ropers *et al.*, 2011). Additionally, the retromer cargo-selective complex also interacts with a protein called FKBP15 (also known as WAFL) that associates with the WASH complex and may modulate actin dynamics on endosomes through further interactions with actin and the WIP (WAS/WASL-interacting protein family member 1) protein (Viklund *et al.*, 2008). The precise role of FKBP15/WAFL in retromer-mediated endosomal protein sorting remains to be determined.

The interaction between the retromer cargo-selective complex and the WASH complex occurs through VPS35 binding to FAM21, an association that requires VPS29 to be bound to VPS35 and is mediated by repeated sequences called LFa motifs in the long unstructured tail of FAM21 (Harbour *et al.*, 2010, 2012; Jia *et al.*, 2012; Helfer *et al.*, 2013). The retromer cargo-selective complex is required for the WASH complex to localize to endosomes and overexpression of just the FAM21 tail can cause endogenous WASH complex to be displaced from the endosome due to competition for binding to VPS35. Recently it has been reported that a mutation in VPS35 that causes an inherited form of Parkinson's disease (Vilariño-Güell *et al.*, 2011; Zimprich *et al.*, 2011) impairs the association of the WASH complex with the retromer cargo-selective complex and results in reduced WASH complex recruitment to endosomes (Zavodszky *et al.*, 2014). The sequential recruitment of the retromer cargo-selective complex and the WASH complex to the endosomal membrane, and the role of retromer in sorting cargo proteins into multiple pathways, is depicted in Figure 3.

The association of the retromer cargo-selective complex with the WASH complex and the interaction of the SNX dimer with the microtubule cytoskeleton means that, in mammals, retromer-mediated endosomal protein sorting is linked to both short range actin-based movement to regulate protein localization within the endosomal membrane and long range microtubule-mediated movement to control the location of the endosome within the cell.

In addition to binding to the retromer cargo-selective complex, the FAM21 tail also associates with a protein called RME-8 (Freeman *et al.*, 2014). The RME-8 protein is a member of the DNAJ domain protein family that often associate

Figure 3 Recruitment and action of the retromer complex. In the three panels the action of the retromer complex is shown sequentially: (a) The retromer cargo-selective complex is recruited to the membrane through binding to Rab7 and SNX3 whilst the sorting nexin dimer binds to PtdIns 3P and can also associate with the dynactin–dynein complex. In (b), the retromer cargo-selective complex recruits the WASH complex through VPS35 binding to the extended unstructured ‘tail’ of FAM21. This enables the WASH complex to promote Arp2/3-mediated branched actin production on endosomal membranes. In (c), actin-stabilized microdomains facilitate sorting of cargo proteins into multiple pathways exiting the endosome.

with chaperone proteins and have roles in regulating assembly of macromolecular complexes. Interestingly, RME-8 (also known as DNAJC13) has been shown to interact with SNX1 (Shi *et al.*, 2009) and loss of RME-8 function alters the kinetics of SNX1 association with endosomes and results in pronounced tubulation of endosomal membranes (Freeman *et al.*, 2014). It has recently been demonstrated that RME-8/DNAJC13 is mutated in an inherited form of Parkinson’s disease (PD) (Vilar-iño-Güell *et al.*, 2014). As both VPS35 and RME-8/DNAJC13 have now been linked to PD and both can associate with the FAM21 tail, it seems possible that the protein–protein interaction network that controls retromer–WASH complex function at endosomes is especially important in the pathology of PD. The interaction of the retromer cargo-selective complex with various accessory proteins, many of which are implicated in neurological disease is shown in Figure 4.

Studies of the role of the WASH complex in endosomal protein sorting have shown that numerous cargo proteins require the WASH complex for their correct localization. The WASH complex has been implicated in the retrieval of the CIMPR from endosomes to the Golgi (Gomez and Billadeau, 2009) and has also recently been linked to trafficking the multi-pass membrane protein ATG9 to autophagosomes (Zavodszky

et al., 2014). Interestingly, however, most of the cargo proteins shown to require WASH complex function traffic in an endosome-to-cell surface pathway (reviewed in Seaman *et al.*, 2013). These proteins include the glucose transporter GLUT-1, the β -adrenergic receptor, which is a G-protein coupled receptor (GPCR) and the $\alpha 5 \beta 1$ integrin protein required for cell spreading. Thus, through the requirement for the retromer cargo-selective complex to mediate the endosomal recruitment of the WASH complex, retromer is involved in sorting cargo proteins for recycling to the cell surface.

Recently another SNX protein, SNX27 has been shown to associate with both the WASH complex and also the retromer cargo-selective complex (Steinberg *et al.*, 2013). The SNX27 protein binds to VPS26 and may participate in cargo selection through the FERM (4.1/ezrin/radixin/moesin) domain present in SNX27 that can recognize, NPxY (Asn-Pro-x-Tyr) motifs present in a number of cargo proteins within the endocytic system (Ghai *et al.*, 2013). Unlike the retromer SNX dimer, SNX27 does not possess a BAR domain and therefore cannot mediate membrane tubulation.

It is important to note that whilst the retromer complex is ubiquitously conserved, many of the accessory proteins that associate with retromer in complex metazoans such as

Figure 4 The retromer cargo-selective complex is the nexus of a protein–protein interaction network that is linked to many neurological disorders. The retromer cargo-selective complex and WASH complex associate with a number of proteins linked to disease, for example, the WASH complex interacts with the Parkinson's disease protein, RME-8 via FAM21 (Freeman *et al.*, 2014). Proteins shown here that are not discussed in the text include Dynamin-2 that associates with the WASH complex (Derivery *et al.*, 2009), Ataxin-1 that can interact with TBC1D5 and FAM21 (Lim *et al.*, 2006), CCDC22 that binds to FAM21 (Harbour *et al.*, 2012) and TTBK2 that is reported to interact with FKBP15 (Pan *et al.*, 2010).

mammals are less well conserved. The TBC1D5 protein is not conserved in yeast, nor is the WASH complex or EHD1 suggesting that retromer can perform its essential function(s) without these accessory proteins. The retromer accessory proteins may therefore provide additional layers of regulation required for 'fine tuning' retromer-mediated endosomal protein sorting – adaptations that have been lost in simple organisms such as yeast.

The Physiological Processes That Depend on Retromer

The sorting of a diverse array of cargo proteins by retromer sets the scene for retromer to contribute to a great many physiological processes. The requirement for retromer in sorting vacuolar and lysosomal hydrolase receptors for retrieval to the Golgi demonstrates the importance of retromer in lysosome biogenesis (Arighi *et al.*, 2004; Seaman, 2004). Developmental pathways that utilize the morphogen Wnt also depend on retromer to ensure the Wnt chaperone protein Wntless is retrieved from endosomes to pick up more Wnt in the Golgi (see Eaton, 2008 for summary). The SorL1 protein associates

with amyloid precursor protein (APP) and controls APP localization within the endocytic system thereby regulating the processing of APP – processing that determines whether APP is cleaved to form the neurotoxic pro-aggregatory $A\beta$ peptide that is causal in Alzheimer disease. SorL1 is a cargo for retromer and therefore retromer has become recognized as a key player in the pathogenesis of Alzheimer disease (for review see Willnow and Andersen, 2013). Indeed studies of neuronal tissue from Alzheimer disease (AD) patients have revealed reduced retromer expression and RNAi-mediated silencing of retromer proteins results in increased production of the $A\beta$ peptide (Muhammad *et al.*, 2008). The key role that retromer-mediated sorting of SorL1 plays in regulating the localization and processing of APP is shown schematically in Figure 5.

In neuronal cells, retromer has been shown to mediate sorting and transport of proteins from endosomes to the cell surface at localized sites thereby contributing to the generating of dendritic spikes – structures that are often associated with synapse formation and synaptic plasticity (Choy *et al.*, 2014). It seems likely that retromer-associated proteins such as the WASH complex will, through an interaction with retromer, play a major role in these processes and hence this may

Figure 5 Retromer function regulates APP processing and therefore is important for Alzheimer disease pathogenesis. The retromer cargo-selective complex can associate with the SorL1 protein that regulates APP localization. Sorting of SorL1-APP by retromer reduces APP residence time in endosomes and thereby protects APP from cleavage by the β -secretase (BACE). The diagram is adapted from Andersen, O.M., Willnow, T.E., 2006. Lipoprotein receptors in Alzheimer's disease. *Trends in Neurosciences* 29 (12), 687–694.

provide some means to explain the neuronal phenotypes (e.g., HSP and ARID) associated with WASH complex dysfunction.

Retromer has been shown to control the localization of the membrane protein Crumbs that is required for the establishment of cell polarity (Pocha *et al.*, 2011). Additionally, in polarized cells, retromer is required for the transcytosis of the polymeric IgA receptor – a protein that mediates the transfer of IgA from blood into bile (Vergés *et al.*, 2004). In addition to regulating protein localization, retromer has also been shown to control the signaling activity of certain GPCRs. Upon ligand binding, the parathyroid hormone receptor (PTHr) is endocytosed in an arrestin-dependent manner. After arrival at the endosome, the signaling activity of the PTHr is down regulated – a process that involves the displacement of the arrestin by retromer, most likely with the VPS26 subunit playing a key role (Feinstein *et al.*, 2011).

A recent proteomic study of retromer-mediated recycling of proteins to the cell surface identified more than 100 membrane proteins that require retromer function for their localization to the plasma membrane including many receptors and signaling molecules (Steinberg *et al.*, 2013). These proteins are likely to participate in a great many physiological processes and therefore retromer is likely to be required for additional processes and mechanisms that have yet to be identified and reported.

Retromer and Disease

The importance of retromer-mediated endosomal protein sorting to the pathogenesis of AD has already been described.

Indeed certain polymorphisms of the gene that encodes the retromer cargo SorL1 have been shown to cause late-onset AD (Rogaeva *et al.*, 2007). Additionally variants of the Rab7a and SNX3 genes have also been linked to late-onset AD (Vardarajan *et al.*, 2012). A rare point mutation in VPS35 that causes Parkinson's disease (PD) has been mentioned previously. Mutants of the WASH complex proteins, strumpellin, and KIAA1033, respectively, cause HSP and ARID. These studies all show how retromer-mediated endosomal protein sorting is key to many neurodegenerative diseases although much remains unknown regarding the patho-physiological processes that result from defective or deficient retromer function.

Various pathogens exploit retromer-mediated endosomal protein sorting for their own ends. For example, the Shiga toxin protein produced by Shigella bacteria utilizes retromer-mediated endosome-to-Golgi retrieval in order to traverse the endocytic system en route to firstly the Golgi and then the endoplasmic reticulum (Bujny *et al.*, 2007). Invasive bacteria such as Salmonella and Legionella also interfere with retromer-mediated endosomal protein sorting as part of the process of pathogenesis (McGourty *et al.*, 2012; Finsel *et al.*, 2013). In the case of Legionella, once inside a cell, the bacteria express a protein called RidL that can bind to VPS29 to inhibit the function of retromer.

Viral pathogens can also interact with or subvert retromer function as recently demonstrated by the finding that the human papilloma virus (HPV) interacts with retromer post-infection (Lipovsky *et al.*, 2013).

Whilst the precise mechanisms that underlie these various pathologies remain to be determined, it seems likely that

interfering in retromer function, or the function of retromer-associated proteins, is likely to lead to mislocalization of many different membrane proteins linked to various physiological processes. There is, therefore, much yet to learn regarding how retromer functions in endosomal protein sorting and how these mechanisms contribute to health and disease and no doubt many exciting discoveries will emerge in the coming years.

Glossary

GTPase Protein that binds to and hydrolyzes the nucleotide GTP.

Membrane fusion The process by which two initially distinct lipid bilayers merge to form one interconnected structure.

Multisubunit tethering complexes Large protein complexes consisting of 3–10 polypeptides, that are used for tethering vesicles to target membranes.

SNARE complex A long four-helical-bundle complex consisting of 3–4 distinct polypeptides, which forms the membrane fusion machinery.

Tethering The process by which a protein or protein complex interacts with two distinct membranes to bridge them at long distances and bring them into closer proximity. Tethering proteins or complexes may also facilitate SNARE complex assembly and membrane fusion.

Vesicular transport Trafficking of proteins and lipids from one cellular compartment to another by means of membrane-enclosed intermediates such as vesicles.

Introduction

Vesicular traffic is the principle mechanism in eukaryotic cells by which proteins and other cargo are transported from one membrane-bounded organelle to another, as well as to the plasma membrane for growth and secretion. A vesicle that has budded and been released for transport will diffuse through the cell or travel along a cytoskeletal track to its target membrane. After a vesicle reaches the target membrane, proteins, and protein complexes known as tethering factors are proposed to facilitate the initial linkage of the membranes (for review, see Whyte and Munro, 2002; Sztul and Lupashin, 2006; Cai *et al.*, 2007; Yu and Hughson, 2010; Heider and Munson, 2012; Brocker *et al.*, 2010; Hong and Lev, 2014).

There are two conserved structural classes of tethering complexes: long coiled-coil tethers (Gillingham and Munro, 2003) and multisubunit tethering complexes (MTCs); (Koumandou *et al.*, 2007; Figure 1). Many coiled-coil tethers are associated with trafficking in the early secretory pathway at the ER and the Golgi complex, including p115/Uso1, GMAP210, GCC185, and giantin, or with endosomal trafficking (e.g., EEA1). The MTCs are also associated with ER and Golgi trafficking events (e.g., Dsl1, transport protein particle (TRAPP), and conserved oligomeric Golgi (COG)); additionally, they serve as tethers for endocytic trafficking pathways (homotypic fusion and vacuole protein sorting (HOPS) class C core vacuole/endosome tethering (CORVET), and Golgi-associated retrograde protein (GARP)), as well as for vesicles traveling to the plasma membrane for exocytosis (exocyst). Beyond the canonical secretory pathway, tethers have also been implicated in other dynamic membrane processes, including cytokinesis, autophagy, and ciliogenesis (Heider and Munson, 2012; Solinger and Spang, 2013; Thellmann *et al.*, 2010; Farkas *et al.*, 2003; Rybak *et al.*, 2014). Furthermore, mutations in several of these complexes are associated with a variety of genetic diseases (Ungar, 2009; Miller and Ungar, 2012; Bonifacino and Hierro, 2011; Lobingier and Merz, 2012; Tornieri *et al.*, 2013; Brunet

and Sacher, 2014b; Huang and Lipschutz, 2014 and references therein). The precise functions of these complexes are still not clear; it is thought that, through their interactions with small GTPases, lipids, and soluble NSF attachment protein receptor (SNARE) proteins, they would bridge the vesicle and target membranes to facilitate tethering and promote vesicle fusion at the correct locations. This broad idea has gained much popularity, although tethering has only been directly observed for a few of these complexes (Chia and Gleeson, 2014; Heider and Munson, 2012; Brunet and Sacher, 2014a; Cao *et al.*, 1998; Sacher *et al.*, 2001; Stroupe *et al.*, 2009).

Interactions with Small GTPases and SNARE Proteins

Regulation or recruitment of tethers is modulated by interactions with a number of small GTPases, including those of the Rab, Arf/Arl, and Rho/Ral families (Stenmark, 2009; Barr and Lambright, 2010; Pfeffer, 2013; Donaldson and Jackson, 2011; Wu *et al.*, 2008). These are small prenylated GTP-binding proteins that interact reversibly with membranes. They are activated by guanine nucleotide exchange factors (GEFs) that catalyze the release of GDP and promote the binding of GTP. GTPase-activating proteins (GAPs) accelerate the hydrolysis of bound GTP to GDP to inactivate the small GTPase function. Thus, Rab GTPases act as molecular switches that are active when bound to GTP and deactivated upon GTP hydrolysis.

Best studied are the connections between active Rab GTPases on vesicles, the tethering complexes, and the SNARE proteins on target membranes to mediate accurate vesicle docking and fusion. The tethers specifically recognize vesicles through their interactions with distinct Rab-GTP proteins. Many tether-Rab interactions have been identified, including the interactions between the HOPS complex and the Rab GTPases Ypt7 (Rab7 homolog) and Vps21 (Rab5) (Plemel *et al.*, 2011; Ostrowicz *et al.*, 2010; Brocker *et al.*, 2012), the

Figure 1 Location of many of the known tethering factors in the eukaryotic membrane trafficking pathways. The names of the coiled-coil proteins and multisubunit tethering complexes are located nearby the trafficking step with which they are associated. The TRAPPIII and exocyst complexes are also implicated in autophagy (not shown).

interaction between GARP and Ypt6 (Siniosoglou and Pelham, 2001), the interaction between the Sec15 subunit of the exocyst complex and the Sec4 GTPase (Rab11) (Guo *et al.*, 1999; Wu *et al.*, 2005), and the COG complex binds multiple Rabs (Miller *et al.*, 2013). The TRAPP complexes also interact with the Rab proteins Ypt1 and Ypt31/32, but appear to function as GEFs to activate these Rabs (Barrowman *et al.*, 2010; Wang *et al.*, 2000; Jones *et al.*, 2000).

To coordinate vesicle recognition with membrane fusion, tethers bind specific SNARE proteins and may regulate SNARE complex assembly and fusion (Hong and Lev, 2014). SNAREs are the core components of the membrane fusion apparatus – SNARE proteins on a transport vesicle (v-SNAREs) pair with cognate SNAREs on the target membrane (t-SNAREs), forming a four-helix bundle complex that brings the two membranes into close apposition for membrane fusion (Sutton *et al.*, 1998; Weber *et al.*, 1998; Sudhof and Rothman, 2009). Although many SNARE-SNARE interactions appear to be specific (McNew *et al.*, 2000), precise temporal and spatial regulation of membrane fusion requires additional layers of regulation ((Furukawa and Mima, 2014) and references therein). Tethering complexes may provide this specificity, as many have been shown to directly interact with partner SNAREs and affect the stability and the rates of SNARE assembly. These include p115 (Shorter *et al.*, 2002), the Dsl1 complex (Diefenbacher *et al.*, 2011; Ren *et al.*, 2009), exocyst (Sivaram *et al.*, 2005), COG (Laufman *et al.*, 2011; Willett *et al.*, 2013), GARP (Perez-Victoria and Bonifacio, 2009), and HOPS and CORVET (Kramer and

Ungermann, 2011; Balderhaar *et al.*, 2013). Regulation of SNARE assembly and fusion may be performed in cooperation with the critical SNARE regulatory Sec1/Munc18 (SM) proteins, which also bind tethering proteins (Morgera *et al.*, 2012; Hong and Lev, 2014). Moreover, several tethers interact with vesicle coat components, suggesting an additional role of tethers in providing specificity prior to SNARE complex assembly (Sztul and Lupashin, 2006; Cai *et al.*, 2007).

Coiled-Coil Tethers

Coiled-coil tethers are large dimeric proteins containing globular heads and long, coiled-coil tails (Gillingham and Munro, 2003). The length and structure of coiled-coil tethers allow them to span distances of more than 200 nm, which is several times the diameter of a typical vesicle. Many coiled-coil tethers, called golgins, associate with the Golgi apparatus and facilitate the trafficking of vesicles traveling from the ER to Golgi or vesicles moving between the cisternae of the Golgi complex. Exemplary members of the golgin family of coiled-coil tethers include p115 (and its yeast homolog Uso1) (Waters *et al.*, 1992; Cao *et al.*, 1998) and its binding partners GM130 (Nakamura *et al.*, 1997) and giantin (Sonnichsen *et al.*, 1998), GCC185 (Luke *et al.*, 2003; Burguete *et al.*, 2008), golgin-84 (Bascom *et al.*, 1999), and GRASP55 (Shorter *et al.*, 1999).

Endosomal trafficking requires coiled-coil tethers such as early endosomal antigen 1 (EEA1); (Simonsen *et al.*, 1998;

Christoforidis *et al.*, 1999; Dumas *et al.*, 2001; Ohya *et al.*, 2009 and references therein). Like other coiled-coil tethers, EEA1 forms a homodimer, and the EEA1 protein contains many different structural domains that impart specific binding properties to the EEA1 complex. For example, the EEA1 homodimer contains N-terminal C₂H₂ zinc finger domains and C-terminal FYVE domains. The FYVE domains bind to phosphatidylinositol 3-phosphate (PI3P); this FYVE-EEA1 interaction recruits EEA1 to the early endosome. The C₂H₂ zinc finger domain of the homodimer binds to the Rab GTPase Rab5, which regulates homotypic tethering (i.e., tethering between endosomes) and fusion of endosomes. Endosomal tethering via EEA1 requires many additional factors, however, and the development of synthetic endosomes has provided new insights into the complexity of tethering and fusion at the endosome. In addition to EEA1 and Rab5, a Rab5 GEF, numerous Rab effectors, lipids, and a variety of SNARE and SNARE-associated proteins are required for efficient homotypic fusion of synthetic endosomes (Ohya *et al.*, 2009).

The structures and multiple binding partners of coiled-coil tethers makes them attractive mediators of tethering. One hypothesis is that coiled-coil proteins of the Golgi may associate to form a 'tentacular cytomatrix' that encapsulates the Golgi apparatus and creates binding sites for vesicles and other molecules that need to associate with the Golgi (Munro, 2011). While some coiled-coil tethers appear to form a vesicle-capturing meshwork, the length of other coiled-coil tethers may facilitate longer-range tethering. For example, p115/Uso1 has a long tail with intervening proline-rich sequences; these proline-rich sequences are relatively flexible and hinge-like, enabling p115/Uso1 to capture vesicles from afar. The p115/Uso1 tether may then bend or collapse upon itself to bring the vesicle and target membrane into close apposition (Yamakawa *et al.*, 1996). Furthermore, the ability of golgins to mediate specificity of vesicle trafficking at the Golgi was recently demonstrated by ectopically targeting different golgins to the mitochondrial membrane – these golgins were able to specifically reroute and capture vesicles bound for the Golgi (Wong and Munro, 2014).

Multisubunit Tethering Complexes

Similar to coiled-coil tethers, MTCs regulate vesicular trafficking at many different stages within the secretory pathway. Nine MTCs (exocyst, COG, CORVET, Dsl1, GARP, HOPS, TRAPPI, TRAPPII, and TRAPPIII) have been identified to date (Koumandou *et al.*, 2007; Brockner *et al.*, 2010; Yu and Hughson, 2010; Perez-Victoria *et al.*, 2010). As the name suggests, each MTC contains several (3–10) different subunits of varying sizes. In general, the individual subunits are more compactly folded than the coiled-coil tethers, which may limit how far the MTCs can reach; EM studies show that several of the MTCs are ~25–30 nm in length (Hsu *et al.*, 1998; Ren *et al.*, 2009; Kim *et al.*, 2006; Yip *et al.*, 2010; Lees *et al.*, 2010; Brockner *et al.*, 2012).

CATCHR Complexes

The exocyst, Dsl1p, COG, and GARP are complexes required for membrane fusion with organelles of the secretory pathway and the plasma membrane. Crystallographic studies of these

complexes showed that subunits from all four complexes have elongated α -helical rod-like structures; these complexes are collectively known as the complexes associated with tethering containing helical rods (CATCHR) family (Yu and Hughson, 2010). The structures of the GARP subunits Vps53 and Vps54 share similar structures to Dsl1, partial structures of Cog2 and Cog4, and four of the eight exocyst subunits, and may have divergently evolved from an ancient ancestor protein (Sivaram *et al.*, 2006; Munson, 2009; Yu and Hughson, 2010). Curiously, similar α -helical bundle structures have been observed for the cargo-binding domain of the type V myosin motors that transport vesicles and RNA (Myo2, Myo4, Myosin V; (Jin *et al.*, 2011)) and the neuronal SNARE regulator Munc13 (Li *et al.*, 2011).

The exocyst is an octomeric complex that regulates many cellular processes, including trafficking and fusion of Golgi-derived vesicles to the plasma membrane, endocytosis, cytokinesis, autophagy, ciliogenesis, and cell migration (for review, see Munson and Novick, 2006; Hertzog and Chavrier, 2011; Liu and Guo, 2011; Heider and Munson, 2012). All of the subunits (Sec5, Sec6, Sec8, Sec10, Sec15, Exo70, and Exo84), except Sec3, are essential in budding yeast, and null mutants of several subunits result in lethality in *Drosophila* and mice, indicating the exocyst's critical role in growth and development. The subunits are localized to sites of polarized growth and secretion. The exocyst subunit Sec15 is proposed to recognize post-Golgi vesicles through interactions with the Rab GTPase Sec4 (Rab11), and the Sec3 and Exo70 subunits bind the plasma membrane through a series of multivalent interactions with phosphatidylinositol 4,5-bisphosphate [PI(4,5)P₂] and the GTPases Cdc42, Rho1, and Rho3. This leads to a model that the assembly of exocyst complexes drives the tethering of secretory vesicles to the plasma membrane (Boyd *et al.*, 2004). Subsequent interactions with the exocytic SNARE proteins and the regulatory protein Sec1 would lead to fusion of the vesicle at proper sites on the plasma membrane.

The Dsl1 complex is located at the ER membrane and binds to Golgi-derived COPI-coated vesicles, and is proposed to function in vesicle tethering, uncoating and SNARE complex assembly (Hughson and Reinisch, 2010; Spang, 2012). Its architecture is simple, as it consists of just three helical subunits – Dsl1, Dsl3/Sec39, and Tip20. A model based on structures of the subunits suggests that the Dsl1 complex is tower-shaped; the base of the tower is anchored to the ER membrane via interactions between the subunits Sec39 and Tip20 with the ER t-SNAREs Sec20 and Use1 (Ren *et al.*, 2009). At the top of the tower is a flexible 'lasso' that can interact with the COPI coat complex of incoming vesicles and tethering these vesicles to the ER.

The COG complex functions as a tether within the Golgi and mediates the retrograde transport of vesicles traveling between the Golgi cisternae (Miller and Ungar, 2012). Mutations in any of its eight subunits (Cog1 to Cog8) cause glycosylation defects and disease in patients and model organisms. The eight subunits are organized into two sets of subunits, or lobes. The first lobe includes Cog2, Cog3, and Cog4; the second lobe consists of Cog5, Cog6, and Cog7. The two lobes are linked by a heterodimer of Cog1 and Cog8 subunits. EM studies show COG as an elongated complex with the subunits assembling into long, thin legs. Although direct

evidence of its role as a tether is still lacking. subunits of the COG complex interact with the Rab GTPases Rab1 (Ypt1) and Rab30, SNARE proteins (e.g., yeast Sed5 and mammalian syntaxin 5), the COPI coat, and SNARE regulators (e.g., the Sec1/Munc18 protein Sly1). COG may also function with coiled-coil tethers of the Golgi to mediate retrograde transport, as interactions between the COG complex and two golgins, p115 and golgin-84, have been observed.

The GARP complex mediates retrograde trafficking from endosomes to the *trans*-Golgi network (TGN) (Bonifacino and Hierro, 2011). GARP consists of four vacuolar protein sorting (Vps) subunits: Vps51, Vps52, Vps53, and Vps54; Vps53, and Vps54 have similar α -helical bundle structures to the other CATCHR family members. GARP, like the other MTCs, also associates with SNARE proteins and small GTPases. In particular, the Vps51 subunit binds to the yeast t-SNARE Tlg1, and the mammalian GARP complex interacts with a host of SNARE proteins including syntaxin 6, syntaxin 16, and Vamp4. GARP also binds to GTP-bound forms of the yeast Rab GTPase Ypt6 and the Arl1 GTPase. The interactions between GARP and the GTPases may mediate GARP binding to the TGN, as depletion of Ypt6 results in the dissociation of GARP from the TGN; however, the functional interplay between GARP and the GTPases has not yet been elucidated.

HOPS and CORVET

The HOPS and CORVET complexes regulate membrane trafficking events at endosomes, vacuoles, and lysosomes (Nickerson *et al.*, 2009; Wickner, 2010; Balderhaar and Ungermann, 2013). Structurally, both complexes are heterohexamers and share a common set of four Class C vacuolar protein sorting (Vps) proteins: Vps11, Vps16, Vps18, and the SM family member Vps33. Each complex has two additional homologous subunits, suggesting that the overall architecture of the HOPS and CORVET complexes is similar. Structurally, all of the Vps-C subunits (with the exception of Vps33) are predicted to contain an amino-terminal β -propeller domain and a carboxy-terminal α -solenoid domain. The Vps11 and Vps18 subunits also contain RING finger zinc-binding domains, potentially mediating protein-protein interactions between the HOPS and CORVET complexes and their binding partners. Interestingly, the predicted Vps-C structures resemble known structures of nuclear pore complex subunits and coat proteins, which also assemble into multisubunit complexes on membranes (Devos *et al.*, 2004).

In addition to the Vps proteins it shares in common with CORVET, the HOPS complex also includes Vps39 and Vps41. It uses these additional subunits, in part, to mediate homotypic fusion of vacuoles. To determine additional factors required for vacuolar fusion, Wickner and colleagues developed a proteoliposome fusion assay to mimic the fusion of two vacuoles *in vitro* (Stroupe *et al.*, 2009). They found that stable tethering and fusion between proteoliposomes required a minimal subset of components: the HOPS complex, the Rab GTPase Ypt7, the vacuolar SNARE proteins (Nyv1, Vti1, Vam3, and Vam7), and the SNARE disassembly proteins Sec17 (α -SNAP) and Sec18 (NSF)/ATP for priming. HOPS appears to coordinate these vacuolar fusion factors by organizing and proofreading SNARE assembly at sites of membrane fusion

and also protects the SNARE complexes from the disassembly proteins Sec17 and Sec18.

The Class C Vps subunits were initially only thought to be part of the HOPS complex; however, these subunits were later identified in association with two non-HOPS subunits, Vps3 and Vps8 (which are homologous to the HOPS subunits Vps39 and Vps41). This alternative complex, CORVET, is required for the fusion of Golgi-derived vesicles with the endosome and homotypic endosomal fusion. CORVET interacts with the early endosomal GTPase Vps21 (Rab5) via both Vps3 and Vps8 and may facilitate membrane fusion by coupling the binding of Vps21 with endosomal SNARE assembly.

TRAPP Complexes

The TRAPP complexes are similar to each other in their composition, but have different roles in vesicular trafficking events (Cai *et al.*, 2007; Sacher *et al.*, 2008; Hughson and Reinisch, 2010; Barrowman *et al.*, 2010). There are three forms of the complex: TRAPPI, TRAPPII, and TRAPPIII. All TRAPP complexes have a common protein core consisting of the proteins Bet3, Bet5, Trs20, Trs23, Trs31, and Trs33. TRAPPI additionally contains the Trs65, Trs120, Trs130, and Tca17/TRAPPC2L subunits, while the TRAPPIII complex is comprised of the core proteins and Trs85. TRAPPI and TRAPPII both function in the secretory pathway in yeast; TRAPPI is required to tether ER-derived vesicles to Golgi membranes, while TRAPPII is postulated to serve as an intra-Golgi complex tether. The recently identified yeast TRAPPIII complex appears to coordinate a membrane tethering event required for autophagy (Lynch-Day *et al.*, 2010).

TRAPPI tethers ER-derived COPII-coated vesicles to the Golgi complex through a direct interaction between the Bet3 subunit of the TRAPPI complex and the vesicle coat protein Sec23. Even though Sec23 is part of the inner layer of the COPII coat, electron microscopy images show that there are gaps in the outer Sec13/31 cage that could allow TRAPPI access to Sec23. The Bet3-Sec23 interaction appears to be essential for vesicle tethering, and this specific interaction allows for the TRAPPI complex to distinguish between COPII-coated vesicles and all other coated vesicles. In addition to their roles as tethers, the TRAPP complexes also act as Rab GEFs for the Rab GTPases Ypt1 and Ypt31/32. Structural data suggests that the central subunits of the TRAPP complexes (Bet3, Bet5, and Trs23) interact with Ypt1 and confer GEF activity. Activation of Ypt1 and Ypt31/32 by the TRAPP complexes may promote tethering and, subsequently, membrane fusion.

Conclusions

The purpose of vesicle tethering is to bring together transport vesicles with their target membranes, perhaps to provide quality control, to prevent diffusion of the vesicle, and to help stimulate membrane fusion. The two major classes of tethers, long coiled-coils and MTCs, share many similar properties, including localization to precise sites of vesicle fusion, binding to specific small GTPases and lipids, and interactions with the SNARE membrane fusion proteins. Many years of genetic and

cell biological experiments identified the players and the relevant membrane trafficking pathways; however, the mechanisms of action of tethers at the molecular level remain to be determined. Indeed, whether or not most of these complexes are in fact tethers needs to be confirmed through direct observation. Higher resolution crystallographic and EM studies are beginning to reveal the structures of these complexes, and our understanding of tethers will benefit greatly from functional reconstitution experiments using purified or biochemically characterized components.

BAR Domains and BAR Domain Superfamily Proteins

Introduction

Eukaryotic cells contain multiple membrane-bound organelles that often require great flexibility in their shape. Accordingly, proteins that are capable of inducing changes in membrane shape are crucial for the organization and function of intracellular organelles, and thus influence important cellular events including endocytic and membrane trafficking, cell cycle, division, and migration. The BIN-Amphiphysin-Rvs (BAR) domain is a sequence of ~200 residues found in proteins that directly influence membrane curvature and shaping. Over 750 BAR domain-containing proteins have been identified so far, in species as diverse as yeast and mammals. However, the primary sequence of BAR domains can vary significantly so that crystal structures were needed initially to confirm that certain (BAR) domains indeed belonged to the same BAR domain family (Tarricone *et al.*, 2001; Peter *et al.*, 2004).

BAR domains typically contain a three-helix coiled-coil region that facilitates dimerization and a positively charged module that is capable of both membrane curvature-sensing as well as membrane binding (Peter *et al.*, 2004). Indeed, loss of dimerization ability renders BAR domain-containing proteins incapable of inducing membrane curvature (Dislich *et al.*, 2011).

Given the wide assortment of membranes that BAR domains must remodel, it is not surprising that these domains have been categorized into subsets, largely dependent on their dimeric structure and ability to induce varying degrees of membrane curvature (reviewed in Frost *et al.*, 2009). In general, the (regular) BAR domains have been divided into 'Classical BAR' domains, 'N-BAR' (amphipathic N-terminal helix) domains, 'BAR-PH' (BAR + pleckstrin homology) domains, and 'PX-BAR' (phox domain-containing) domains (see Figure 1). Whereas the classical BAR domains have the highest level of intrinsic curvature, the N-BAR, pleckstrin homology-containing BAR proteins (PH-BAR), and PX-BAR domains all contain an additional membrane binding domain (e.g., the phosphatidylinositol-4,5-bisphosphate-binding PH domain) (Figure 2).

The largest family of BAR domains is the F-BAR (FCH-BAR-Fes/CIP4 homology-BAR) domain group (Figure 3). These F-BAR domains induce positive curvature (similar to BAR domains), but individual members differ greatly in their degree of curvature induction. In contrast, the I-BAR proteins (Figure 4) generate negative curvature, allowing the cell to extrude membranes (Ahmed *et al.*, 2010), whereas the PinkBAR (planar intestinal- and kidney-specific BAR) domain has no intrinsic curvature and is thought to serve in scaffolding other proteins on flat membrane surfaces (Pykäläinen *et al.*, 2011).

Key BAR Domain-Containing Proteins and Their Cellular Functions

Many BAR domain superfamily proteins contain additional domains that regulate their intracellular functions. For example,

the SH3 domain recognizes proline-rich domains (PRDs) found in actin nucleation promoting factors (NPFs) and in the endocytic regulatory GTPase, dynamin (Suetsugu and Gautreau, 2012). Some BAR domain proteins (endophilin, amphiphysin, and syndapin/PACSIN) also bind to the lipid phosphatase synaptojanin via their SH3 domain (Milosevic *et al.*, 2011; Qualmann *et al.*, 1999). The interaction of BAR domain proteins with NPFs induces membrane protrusions and lamellipodia/filopodia generation, or invaginations leading to clathrin-coated pits (CCPs) and/or caveolae formation. Other combinations of functional domains present in the BAR domain superfamily include the PH and PX domains (as noted above), catalytic domains such as Rho family GTPase guanine exchange factor (GEF) and GTPase activation protein (GAP) domain, tyrosine (Tyr)-kinase domain as well as many protein-protein interaction domains (see Table 1 for a list of well-characterized BAR domain superfamily proteins).

Role of BAR Proteins in Regulating NPF-Mediated Actin Assembly

A dynamic actin cytoskeleton is required to generate forces and induce cell membrane deformation to facilitate various developmental processes, including collective cell migration and tissue formation. Moreover, the fundamental process of endocytosis also requires force generated by the actin cytoskeleton to drive membrane invagination, constricting the neck of these newly formed vesicles and driving the vesicles away from their site of formation (Romer *et al.*, 2010). The rate-limiting step for actin filament polymerization is nucleation or formation of stable actin multimers. This requires the presence of nucleation factors such as the actin-related proteins 2/3 (Arp2/3) complex, formins, and tandem-monomer-binding nucleators (Pollard, 2007). However, in isolation the Arp2/3 complex is an ineffective nucleator that requires binding to preexisting actin filaments and to NPFs. Mammalian cells express several NPFs, such as Wiskott-Aldrich syndrome protein (WASP), neuronal WASP (N-WASP), WASP and verprolin homologs (WAVEs), WASP homolog-associated with actin, membranes and microtubules (WHAMM), WASP and Scar homolog (WASH), and junction mediating regulatory (JMY) protein (Takenawa and Suetsugu, 2007).

NPFs of the WASP and WAVE families contain a conserved C-terminal verprolin-homology domain-cofilin-homology domain-acidic domain (VCA) that is critical for their role in actin filament assembly. Actin nucleators such as Arp2/3 complex are activated by binding to the CA region of NPFs and to the side of actin filaments (Padrick and Rosen, 2010). Tissue-specific NPFs, such as WASP (which is expressed in hematopoietic cells), and ubiquitously expressed N-WASP normally adopt an auto-inhibited conformation in which the VCA region displays an intramolecular interaction with its central GTPase-binding domain rendering it inaccessible to the

Figure 1 Structures of BAR domains from different subfamilies. All structures are depicted as dimers (cyan and orange) (scale bar 130 Å). The black line underneath each structure was introduced to show the intrinsic curvature of each domain. (a) Left, above: side view of the BAR domain of arfaptin 1 (pdb ID 1I49). BAR domains exhibit the highest positive curvature within the BAR superfamily. Classic BAR domains are further subdivided based on additional membrane binding domains. For clarity, different BAR domains are shown as top view. The N-BAR domain contains a N-terminal helix (yellow and green) and a second set of amphipathic helices known as 'insert helices' (orange and cyan). APPL1 (right, above) is an example of a PH-BAR domain that contains an additional pleckstrin homology domain (PH) (pdb ID 2Z00). Lastly, PX-BAR proteins (right, below), such as sorting nexin 9 (SNX9, pdb ID 2RAI), are comprised of a phox-homology domain (PX) and a BAR domain. (b) Side view of the F-BAR domain from FBP (pdb ID 2EFL) exemplifies a shallow, positive curvature that is typical for this subfamily. (c) The Pinkbar is the only instance of a BAR protein that promotes zero curvature; its BAR domain shows no intrinsic curvature (pdb ID 3OK8). (d) I-BAR domain proteins are the only subfamily that can bend membranes to generate structures with negative curvature (IRSp53, pdb ID 1Y20). Arp2/3 complex (Padrick and Rosen, 2010). This inactive conformation is further stabilized by interaction of WASP with WASP-interacting protein (WIP) family members (de la Fuente *et al.*, 2007). Interaction of WASP/N-WASP with phosphoinositides and cell division control protein 42 homolog (Cdc42), a member of the Rho GTPase family, is crucial to relieving this auto-inhibition and in turn for stimulate Arp2/3 complex-mediated actin polymerization (Rohatgi *et al.*, 1999).

To further delineate how factors such as Cdc42 are physiologically regulated, Ho and colleagues identified a novel protein, Toca-1 (transducer of Cdc42-dependent actin assembly), that was required for the full Cdc42-induced activation of the WIP–WASP complex (Ho *et al.*, 2004). Toca-1 is a member of the F-BAR family of proteins that has two other homologs, CIP4 (cell division cycle 42-interacting protein 4) and FBP17 (formin-binding protein 17) (Itoh *et al.*, 2005).

The presence of the F-BAR domain is the hallmark of this family of proteins and CIP4 was one of the first vertebrate F-BAR proteins identified (Gyuris *et al.*, 1993). Besides their N-terminal F-BAR domains, these proteins contain a central HR1 (protein kinase C-related kinase homology region 1) domain that binds to Rho GTPases, and a C-terminal SH3 domain that recognizes PRD regions in NPFs, including WASP/N-WASP (Ho *et al.*, 2004; Aspenstrom 1997). The importance of NPF binding to SH3 domains of F-BAR proteins is reflected by the fact that mutations of the PRDs, cause X-linked neutropenia by disrupting the auto-inhibition of WASP (Devriendt *et al.*, 2001).

Based on recent studies, it has been suggested that the F-BAR-mediated NPF activation is strongly enhanced in the presence of liposomes with specific curvature, and surprisingly activation can occur even in the absence of Cdc42 (Takano *et al.*, 2008). This leads to the notion that the primary role of F-BAR proteins is to recruit the NPFs to membranes of specific curvature rather than playing a direct role in their activation. EFC/FCH-BAR homologs from *Drosophila melanogaster*, *Caenorhabditis elegans*, and vertebrates, also bind and recruit WASP, as well as the related WASP family WAVE/suppressor of cAR (SCAR), to membranes (Fricke *et al.*, 2009; Giuliani *et al.*, 2009). Several studies have demonstrated the role of the CIP4 family in diverse cellular processes, including cell migration, actin pedestals induced by intracellular bacteria, formation

of podosomes, filopodia, and phagocytic cup biogenesis in macrophages (Tsuboi *et al.*, 2009; Pichot *et al.*, 2010; Campellone *et al.*, 2012). The role of this family in clathrin-mediated endocytosis is discussed below. Several other F-BAR proteins, including PACSIN, srGAPs, PSTPIPs, and nostrin, bind WASP family members via their SH3 domains and regulate actin remodeling (Suetsugu and Gautreau, 2012). PACSIN (protein kinase C and casein kinase 2 substrate in neurons)/syndapin was initially identified as a dynamin interaction partner; however later studies showed that its SH3 domain can bind to both dynamin and N-WASP (Qualmann *et al.*, 1999; Qualmann and Kelly, 2000). Syndapin has three isoforms that are expressed in a tissue-specific manner and regulate endocytosis (Modregger *et al.*, 2000). Syndapin-N-WASP complexes can drive local cortical actin polymerization, as well as induce filopodia formation at the cell surface. The primary function of syndapins is thought to couple dynamin-mediated vesicle fission with Arp2/3-complex-dependent F-actin nucleation, thus linking endocytosis and actin dynamics (as discussed below). Syndapins have also been linked to other endocytic pathways and trafficking events in the cell, including caveolae-mediated endocytosis, transport at the trans-Golgi network and endocytic recycling (Senju *et al.*, 2011; Kessels *et al.*, 2006; Giridharan *et al.*, 2013).

Unlike CIP4 family members that activate N-WASP by recruiting both N-WASP and Cdc42 in close proximity to each

other, members of the srGAP (Slit-Robo Rho GTPase activating protein) family of F-BAR proteins negatively regulate actin polymerization by inactivating the Rho GTPases due to the presence of the RhoGAP domain. The srGAPs were originally identified as proteins interacting with the intracellular domain of Robo, receptor for the neuronal repellent factor, Slit (Wong *et al.*, 2001). The role of the Slit-Robo system has been demonstrated in repulsion of motor and olfactory bulb axons in mammals, repulsion of migratory neurons, and inhibition of leukocyte chemotaxis (Wu *et al.*, 2001). The srGAP family consists of three members, srGAP1, srGAP2, and srGAP3 (Wong *et al.*, 2001). *In vitro* studies indicate that srGAP1 modulates the Slit-Robo-dependent repulsive cues in neuronal

migration through inactivation of Cdc42 (Wong *et al.*, 2001). SrGAP2 negatively regulates neuronal migration through the ability of its I-BAR domain to induce filopodia formation (Guerrier *et al.*, 2009). SrGAP3 (also known as mental-disorder associated GAP protein) can regulate Rac and Cdc42 activity and inhibit Rac-dependent neurite outgrowth and may be involved in severe X-linked mental retardation (Endris *et al.*, 2002).

Typically, activation of WASP/WAVE family member NPFs requires their binding to Rho GTPases via their central GTPase-binding domain. However, in T lymphocytes, T cell antigen receptor-induced actin polymerization occurred normally in WASP^{-/-} mice expressing a WASP transgene lacking

Table 1 Well-characterized BAR domain proteins and their functions

the cdc42-binding domain. In contrast, the phosphorylation of a tyrosine residue of WASP by Fyn kinase was absolutely required for WASP effector activities in T cells (Badour *et al.*, 2004). The exclusively hemopoietic F-BAR family member, PSTPIP1 (proline-serine-threonine phosphatase interacting protein 1), interacts with WASP via its SH3 domain and regulates phosphorylation-dependent activation of WASP in T lymphocytes (Côté *et al.*, 2002). PSTPIP1 is a cytoskeletal scaffold protein that binds to protein tyrosine phosphatase (PTP)-PEST and allows the phosphatase to dephosphorylate WASP, thus inhibiting WASP-mediated actin polymerization and formation of the immunological synapse (Badour *et al.*, 2004; Côté *et al.*, 2002). PSTPIP1 also regulates motility of neutrophil-like cells and its ectopic expression drives filopodia-like membrane extensions (Chitu *et al.*, 2005). Mutations in PSTPIP1 cause PAPA (pyogenic sterile arthritis, pyoderma gangrenosum, and acne) syndrome, an autoinflammatory disease with severe skin and joint involvement (Wise *et al.*, 2002). The molecular basis of this disease and how PSTPIP1 is linked to inflammatory signaling is not understood. Other F-BAR proteins such as GAS7 (growth arrest-specific protein) and Nostrin also contain SH3 domain that bind to N-WASP and regulate actin dynamics in the cell (Suetsugu and Gautreau, 2012). GAS7 uniquely contains an N-terminal SH3 domain and is required for neurite outgrowth in cerebellar neurons and can induce formation of cellular protrusions in NIH3T3 cells (You and Lin-Chao, 2010; She *et al.*, 2002). Nostrin was identified as an interaction partner for endothelial nitric oxide synthase (eNOS) and facilitates its internalization by coordinating dynamin and N-WASP activity (Icking *et al.*, 2005). Recently, it was demonstrated that Nostrin is required for Rac1 activation and it mediates endothelial cell migration to promote angiogenesis in zebrafish (Kovacevic *et al.*, 2012).

In addition to the F-BAR proteins that bind WASP/WAVE family members, BAR, N-BAR, PX-BAR, and I-BAR proteins also bind and regulate actin polymerization at specific cellular locations. For example, proteins such as amphiphysin, endophilin, and SNX9 are involved in clathrin-mediated endocytosis (CME) and regulate actin polymerization at the neck of CCPs, allowing the branched actin network to assist dynamin during vesicle scission (Qualmann *et al.*, 2011). The role of these proteins in CME will be discussed below. Members of the I-BAR protein family, such as IRSp53 (insulin receptor substrate protein of 53 kDa), also bind to WASP/WAVE NPFs and are primarily implicated in inducing negative curvature leading to formation of lamellipodial and filopodial membrane protrusions (Suetsugu *et al.*, 2006). IRSp53 can bind to both N-WASP and WAVE NPFs via its SH3 domain (Takenawa and Suetsugu, 2007; Miki *et al.*, 2000). Overexpression of full-length IRSp53 induces filopodia formation by binding and recruiting N-WASP. However, this seems to be independent of the VCA domain of N-WASP, as N-WASP deleted of its VCA domain is still able to mediate IRSp53-dependent induction of filopodia (Lim *et al.*, 2008). The SH3 domain of IRSp53 can also bind to the formin, mDia1, and to the actin elongation factors, mammalian enabled protein (MENA) and VASP, which promote actin polymerization without branching, and actin bundling required for filopodia formation (Scita *et al.*, 2008). IRSp53 also has a cell division control protein 42 homolog (CDC42)-Rac interactive binding

region (CRIB) that is required for Cdc42-induced filopodia formation (Scita *et al.*, 2008).

Other I-BAR proteins such as MIM (missing-in-metastasis) and ABBA (actin-bundling protein with BAIAP2 homology) lack an SH3 domain, but instead have a C-terminal WH2 (WASP-homology 2) domain that mediates direct binding to actin monomers (Mattila *et al.*, 2003). MIM was first identified as a tumor suppressor that is down-regulated in bladder carcinoma cell lines (Lee *et al.*, 2002). Overexpression of MIM is associated with changes in cell shape, driving lamellipodia formation, an increase in membrane ruffles and promoting metastatic ability of cancer cells by engaging Rho GTPases and cofilin in this process (Xie *et al.*, 2011). Another BAR domain protein involved in formation of membrane protrusions such as invadopodia and podosomes is ASAP1 (ArfGAP with SH3 domain, ankyrin repeat and PH domain), a tandem BAR-PH domain-containing protein with an ArfGTPase activating domain (ArfGAP) that catalyzes hydrolysis of GTP-bound Arf proteins (Kam *et al.*, 2000). ASAP1 interacts with Src kinase, which phosphorylates a crucial tyrosine residue required for ASAP1 function in podosome formation (Brown *et al.*, 1998). PinkBAR, an epithelial tissue-specific I-BAR protein has a unique flat BAR domain and thus cannot induce curvature but rather deforms phosphoinositide-containing membranes into planar structures (Pykäläinen *et al.*, 2011). PinkBAR localizes to specific cellular locations such as the tight junctions in kidney and intestinal epithelial cells and is implicated in maintaining the integrity of these intercellular connections (Pykäläinen *et al.*, 2011).

BAR Domain Proteins as Regulators of Intracellular Transport

One of the most well-studied functions of BAR domain proteins is during clathrin-mediated endocytosis. During CME, the plasma membrane of the cell undergoes sequential stages of remodeling with increasing membrane curvature. It has been suggested that BAR domain proteins can induce/sense this membrane curvature, and create macromolecular platforms that recruit different binding partners. The recruitment of actin, dynamin, and synaptojanin thus coordinate the different stages of CME such as membrane invagination, clathrin coat formation, actin nucleation, fission, and uncoating (Suetsugu and Gautreau, 2012). It is interesting to speculate that the spatiotemporal recruitment of different BAR proteins to these increasingly curved membranes is predetermined by the intrinsic curvature of their BAR domains. Recent studies have revealed that for some, but not all BAR domain proteins, this correlation holds true (Taylor *et al.*, 2011). For instance, members of F-BAR family, Fer/Cip4 homology domain-only proteins 1 and 2 (FCHo1/2), which have a very shallow curvature, are recruited early during CME and are thought to induce/stabilize the shallow invagination of the plasma membrane marking the sites for CCP formation (Henne *et al.*, 2007). In agreement with this, overexpression of FCHo protein increases nucleation of CCPs while knockdown of FCHo leads to reduced formation of CCPs (Henne *et al.*, 2010). However, compelling studies in zebrafish demonstrate that FCHo activity is not required for clathrin-coat nucleation and that adaptor protein-2 (AP-2) depletion leads to a broader and earlier

developmental defect that is independent of FCHo1/2 (Umasankar *et al.*, 2012).

N-BAR family proteins, amphiphysin and endophilin as well as the F-BAR protein Syndapin are recruited to late stages of clathrin-coated vesicle formation prior to scission, as they have a very narrow curvature which fits with that of the deeply invaginated coated pits (Taylor *et al.*, 2011). Amongst these three BAR-domain proteins, endophilin has the sharpest curvature followed by amphiphysin. Syndapins have a shallower curvature of ~ 50 nm circle diameter (Peter *et al.*, 2004). However, their near simultaneous recruitment to coated invaginations is surprising and suggests that other factors besides intrinsic BAR domain curvature guide their temporal association with CCPs (Taylor *et al.*, 2011). Similarly, the biphasic recruitment of the F-BAR subfamily CIP4/FBP17/Toca-1 before and after vesicle scission (Taylor *et al.*, 2011) does not correlate with their BAR domain structure alone, suggesting roles for other factors regulating recruitment of BAR domain proteins during CME. It is interesting to note that recruitment of these BAR domain proteins correlates with the recruitment of their common binding partners, the small GTPase dynamin and N-WASP (Qualmann *et al.*, 1999, 2000; Ho *et al.*, 2004; Itoh *et al.*, 2005; David *et al.*, 1996).

The prototype N-BAR proteins, endophilin and amphiphysin, regulate receptor-mediated endocytosis and synaptic vesicle recycling (Gad *et al.*, 2000; Verstreken *et al.*, 2003; Schuske *et al.*, 2003). Endophilin interacts with dynamin, N-WASP, and synaptojanin via its SH3 domain while amphiphysin can bind to clathrin, the AP-2 adaptor complex, dynamin, and synaptojanin (Verstreken *et al.*, 2003; McMahon *et al.*, 1997). Initial loss-of-function studies of endophilin A in worms and flies revealed the presence of CCPs devoid of dynamin rings, suggesting a role for endophilin A in the recruitment of dynamin to later stages CCP life spans (Gad *et al.*, 2000; Schuske *et al.*, 2003). However, results from knockout mice of all three endophilin A isoforms demonstrate that endophilins are involved in synaptic vesicle recycling and uncoating of clathrin-coated vesicles rather than dynamin-dependent scission of clathrin-coated vesicles. Uncoating of clathrin-coated vesicles (CCVs) is regulated by dephosphorylation of phosphatidylinositol-4,5-bisphosphate to phosphatidylinositol-4-monophosphate by the phosphatase synaptojanin, whose recruitment to CCPs and control of enzymatic activity is regulated by its interaction with the endophilin A SH3 domain (Milosevic *et al.*, 2011). It is now generally accepted that the main role of endophilin A during clathrin-mediated endocytosis is to regulate synaptojanin, but not dynamin recruitment to CCPs.

Amphiphysin I, the first structurally characterized BAR domain protein, has an N-terminal BAR domain, a central alanine- and glutamate-rich domain harboring a proline-rich motif and hydrophobic region, and a C-terminal SH3 domain (Peter *et al.*, 2004). Initial studies had identified dynamin and synaptojanin as two major binding partners of amphiphysin's SH3 domain from brain extracts (David *et al.*, 1996). Interestingly, amphiphysin I SH3 domain is also able to mediate an intramolecular interaction with its own central proline-rich motif, which is important for regulating its interaction with other binding partners such as dynamin and synaptojanin (Farsad *et al.*, 2003). Amphiphysin I also interacts with the

α subunit of AP-2 and clathrin heavy chain via an interaction interface known as the CLAP (clathrin/AP-2 binding) domain (McMahon *et al.*, 1997). Initial studies on the SH3 domain of amphiphysin revealed its essential role in recruiting dynamin to endocytic pits, both in neuronal and non-neuronal cells (Shupliakov *et al.*, 1997). Expression of the amphiphysin I SH3 domain (but not SH3 domains from other proteins that bind dynamin via other motifs distinct from the amphiphysin 1 SH3 domain) inhibits receptor-mediated endocytosis. This effect was specifically due to inhibition of dynamin, as its overexpression neutralized the effect of the amphiphysin1 SH3 domain and restored endocytosis (Wigge *et al.*, 1997). Similarly, microinjection of the GST-CLAP domain of amphiphysin I blocked the early stages of clathrin-mediated endocytosis, suggesting that the association of amphiphysin with both AP-2 and clathrin is essential for endocytosis (McMahon *et al.*, 1997). Interestingly, analysis of brain extracts from amphiphysin I knockout mice revealed reduced membrane associations between AP-2, clathrin, and synaptojanin, but surprisingly not dynamin (Di Paolo *et al.*, 2002). This contradicted earlier work suggesting that amphiphysin is critical for dynamin recruitment to CCPs and inducing dynamin's GTPase activity (Shupliakov *et al.*, 1997). However, further analysis revealed reduced association of the dynamin1 PRD with the clathrin heavy chain, and AP-2 in the amphiphysin I knockout mice, but these interactions were restored upon expression of recombinant amphiphysin I (Di Paolo *et al.*, 2002). Thus while amphiphysin was not required for dynamin's association with membranes, it was important to link dynamin to clathrin and AP-2 on CCPs.

In non-neuronal cells, the PX-BAR protein SNX9 is critical for dynamin recruitment to CCP (Lundmark and Carlsson, 2004). SNX9 is a member of sorting nexin family of proteins, which has 33 members in mammals, several of which are involved in membrane trafficking (Worby and Dixon, 2002). While most SNX family members contain BAR and PX domain, the SNX9 subfamily (which includes SNX18 and SNX33) contains an additional SH3 domain that binds to dynamin and N-WASP and is implicated in clathrin-mediated endocytosis (Worby and Dixon, 2002). SNX9 knockdown in HeLa cells leads to the reduced internalization of transferrin receptor. Moreover, in non-neuronal cells, SNX9 binds and recruits dynamin to the plasma membrane and stimulates its GTPase activity, thus suggesting a role for SNX9 during CME vesicle scission (Lundmark and Carlsson, 2004). SNX9 also participates in N-WASP activation leading to Arp2/3 complex-mediated actin nucleation in the presence of liposomes (Yarar *et al.*, 2007). Other SNX family members are involved in the later stages of endocytic transport as discussed below.

Similar to the BAR and N-BAR proteins mentioned above, syndapin I and closely related F-BAR family members CIP4, FBP17 and Toca-1 also interact with dynamin and N-WASP to regulate CME (Itoh *et al.*, 2005). Syndapin I is predominantly expressed in neurons and is thought to play a critical role in recruiting dynamin to the plasma membrane, thereby regulating its function during synaptic vesicle recycling (Qualmann *et al.*, 1999). Both proteins are simultaneously recruited to CCPs, as revealed by TIRF analyses (Taylor *et al.*, 2011). Microinjection of antibodies either against full-length syndapin, or its SH3 domain, blocks scission of synaptic vesicles, an

effect similar to blocking dynamin function (Andersson *et al.*, 2008). Syndapin I knockout mice phenocopy several defects found in the dynamin I knockout mice, further reinforcing the notion that syndapin I regulates dynamin function (Ferguson *et al.*, 2007). The F-BAR subfamily CIP4/FBP17/Toca-1 proteins regulate endocytosis of transferrin receptor, as demonstrated by single, double, or triple knockdown of the proteins in cultured cells (Itoh *et al.*, 2005). Targeted deletion or knockdown of these proteins in flies and worms has revealed their role in endocytosis of E-cadherin and the yolk receptor respectively (Fricke *et al.*, 2009; Giuliani *et al.*, 2009; Leibfried *et al.*, 2008). Interaction of CIP4/FBP17/Toca-1 and syndapin I with N-WASP is thought to link actin cytoskeleton dynamics with clathrin-coated vesicle detachment and driving the vesicle away from the plasma membrane after its scission (Suetsugu and Gautreau, 2012; Itoh *et al.*, 2005; Qualmann *et al.*, 2011).

There are several other multiple domain-containing BAR proteins that apparently function in endocytic transport. One example is Tuba, which has four N-terminal SH3 domain that bind to dynamin, a central Dbl homology (DH) domain that functions as a GTPase exchange factor for Cdc42, a BAR domain and two C-terminal SH3 domains that bind to N-WASP and Ena/VASP, proteins that regulate actin polymerization (Salazar *et al.*, 2003). The DH domain of Tuba is unique amongst the proteins containing DH domains as it is followed by a BAR domain and not a PH domain, suggesting that Tuba might provide a functional link between dynamin, Rho GTPase signaling, the actin cytoskeleton, and endocytosis. Tuba also localizes to and stimulates dorsal ruffle formation in a melanoma cell line and controls junctional organization of simple epithelial cells (Otani *et al.*, 2006; Kovacs *et al.*, 2006). Another example is the PDZ and BAR domain protein PICK1 (protein interacting with C-kinase 1), which is highly expressed in the central nervous system and was identified as a protein interacting with PKC α (Staudinger *et al.*, 1995). PICK1 also interacts with several critical neuronal receptors, including α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type ionotropic glutamate receptors (AMPA receptors), the metabotropic glutamate receptor mGluR7 as well as various neurotransmitter transporters including the dopamine transporter (DAT), the norepinephrine transporter, and the Glt1b glutamate transporter (Höhne *et al.*, 2011; Jin *et al.*, 2006). For several of these receptors, it has been suggested that PICK1 regulates their endocytosis by direct binding, or by regulating their PKC α -dependent phosphorylation, which in turn controls their neuronal functions important for synaptic plasticity (Hanley, 2008).

While the BAR domain proteins discussed thus far regulate initial stages of endocytic transport at the plasma membrane, and their BAR domains have affinity toward the phospholipid phosphatidylinositol-4,5-bisphosphate, BAR domain proteins with either a PH or PX functional module (such as APPL1 and sorting nexins) display affinity toward phospholipid phosphatidylinositol-3-monophosphate, a lipid enriched on early endosomes. Early endosome localization of APPL1 and its isoform APPL2 is regulated by their interaction with the endocytic Rab GTPase, Rab5, which regulates vesicle fusion at the early endosome (Miaczynska *et al.*, 2004). APPL1 and APPL2 are unique endocytic adaptor that shuttle between endosomes and nucleus in response to extracellular stimuli

such as EGF. In the nucleus APPL proteins interact with the nucleosome remodeling and histone deacetylase complex (NuRD/MeCP1) and thus regulate cell proliferation (Miaczynska *et al.*, 2004). Sorting nexins were originally identified as proteins interacting with EGFR (Kurten *et al.*, 1996). Of the 33 members, only nine have the BAR domain described as SNX-BAR proteins (Worby and Dixon, 2002). SNX1, the most well-characterized member of the SNX-BAR subfamily is part of large multiprotein complex known as the retromer and it is implicated in cargo retrieval along the endosome-to-Golgi pathway, a function that is conserved from yeast to mammals (Worby and Dixon, 2002). Endogenous SNX1 is greatly enriched on highly tubular membranes that emanate from early endosomes (Griffin *et al.*, 2005). Both the PX domain and the curvature-sensing BAR domain are involved in correctly targeting SNX1 to these intracellular membranes and regulating its function in retrograde trafficking (Worby and Dixon, 2002; Griffin *et al.*, 2005). There is growing evidence suggesting that other members of the SNX family (i.e., SNX4 and SNX9) regulate membrane trafficking from the plasma membrane to endosomes by recognizing lipids enriched at the plasma membrane (Worby and Dixon, 2002).

Finally, several recent studies of ubiquitously expressed isoforms of the brain-specific BAR domain proteins amphiphysin I and syndapin I, amphiphysin II, and syndapin II, have revealed their roles in the transport of cargo from the endocytic recycling compartment to the plasma membrane. These proteins associate with C-terminal Eps15 homology domain (EHD) family of proteins to regulate receptor recycling (Giridharan *et al.*, 2013; Pant *et al.*, 2009; Braun *et al.*, 2005).

Role of BAR Proteins in Regulating Signaling

While BAR domain-containing proteins are generally associated with regulating cytoskeletal dynamics and endocytic trafficking, a subgroup of BAR-domain proteins such as Fps/Fes (fps, Fujinami poultry sarcoma; fes, feline sarcoma) and Fer (Fes-related protein) play a crucial role in regulating signaling pathways. Fps/Fes and Fer are structurally unique members of the non-receptor protein tyrosine kinase family and were first isolated as oncogenes from avian and feline retroviruses (Beemon, 1981). Subsequently, the cellular homolog of the Fps/Fes oncogene was identified in several species, including humans and mice, where they play key roles in inflammatory pathways, hemostasis, and innate immunity (Greer, 2002). Fes and Fer proteins contain an N-terminal F-BAR domain, an F-BAR extension (FX) domain that binds to phosphatidic acid, a SH2 domain that recognizes phosphotyrosine motifs, and a C-terminal kinase domain. Early studies on the viral Fps pointed to an important role of its N-terminal region in regulating transforming activity and membrane localization (Brooks-Wilson *et al.*, 1989). Moreover, the F-BAR domains of Fes and Fer are necessary for their oligomerization, which potentiates their *trans*-autophosphorylation activity. However, whether oligomerization is required for their catalytic activity is not known (Greer, 2002). The Fes F-BAR domain can bind phosphoinositides and induce liposome tubulation *in vitro* (Zirngibl *et al.*, 2001). The F-BAR domain in Fer interacts with the adherens-junction protein p120catenin,

and overexpression of Fer results in increased phosphorylation of p120catenin and dissolution of adherens junctions and cell–cell adhesion (Piedra *et al.*, 2003). The SH2 domain of Fps/Fes and Fer is thought to mediate phosphotyrosine-dependent interactions with several receptors such as EGFR and PDGFR, as well as signaling molecules such as PI3K and insulin receptor substrate-1 (Iwanishi *et al.*, 2000). Moreover structural insights into the SH2 domain from Fes have suggested that the SH2 domain tightly interacts with the kinase domain, and activation of Fes kinase activity is closely coupled to SH2–kinase–ligand interactions (Filippakopoulos *et al.*, 2008). The kinase domain of Fps/Fes phosphorylates, among other substrates, the protein BCR (breakpoint cluster region) (Maru *et al.*, 1995), which has GEF activity toward Rho GTPase and RhoA and GAP activity toward Rac1, suggesting that Fps/Fes can regulate cytoskeletal dynamics by controlling BCR phosphorylation (Chuang *et al.*, 1995). Other functions of Fes and Fer include vesicular trafficking and receptor internalization-mediated phosphorylation of protein substrates such as cortactin, platelet/endothelial cell adhesion molecule1 (Pecam-1), and β -catenin, as well as regulating cell migration, platelet activation, and leukocyte extravasation at sites of inflammation (Greer, 2002).

Glossary

14-3-3 proteins Family of proteins with protean functions, including acting as a scaffold for tubulation and fission from the Golgi complex.

Adaptor protein 180 (AP180) AP180 N-terminal homology (ANTH)-domain containing protein which binds phosphoinositide 4,5 bisphosphate (PtdIns(4,5)P₂) and clathrin to promote endocytosis.

Adaptor protein 2 (AP2) Multimeric protein complex, which interacts with phosphoinositides by positively charged domains and clathrin to promote endocytosis.

Adaptor protein containing pleckstrin homology (PH) domain phosphotyrosine binding (PTB)-domain and leucine zipper motif (APPL) Rab5-binding proteins which are on a subset of very early endosomes and are a precursor to phosphoinositide-3-phosphate (PtdIns(3)P)-positive early endosomes.

Adenosine diphosphate(ADP)-ribosylation factor 1 (Arf1) Small guanosine 5'-triphosphatase (GTPase) protein which mediates coat protein dynamics and participates in coincidence binding of effector proteins at the Golgi together with phosphoinositide 4 phosphate (PtdIns(4)P).

Atg12-Atg5-Atg16L complex It regulates autophagosome maturation by promoting the lipidation of microtubule associated protein light chain 3 (LC3).

Calcium-dependent activator protein for secretion (CAPS) PtdIns(4,5)P₂-binding protein involved in plasma membrane exocytosis by priming calcium-dependent activator vesicles and organizing SNARE proteins.

Ceramide trafficking protein (CERT) PH-domain containing protein which binds PtdIns(4)P and is involved in endoplasmic reticulum to Golgi trafficking of ceramide.

Class I PI3-kinase (PI3KC) Phosphoinositide kinase which catalyzes PtdIns(4,5)P₂ to phosphatidylinositol (3,4,5)-trisphosphate (PtdIns(3,4,5)P₃).

Class II PI3-kinase (PI3KC2A/PI3KC2 α) Phosphoinositide kinase which catalyzes PtdIns to PtdIns(3)P and PtdIns(4)P to phosphatidylinositol (3,4)-bisphosphate (PtdIns(3,4)P₂).

Class III PI3-kinase (PI3KC3) Phosphoinositide kinase which catalyzes PtdIns to PtdIns(3)P.

Class III PI3-kinase complex Autophagy initiation complex of Class III PI3-kinase (Vps34)-Beclin-1(Atg6)-Vps15-Atg14L.

Class II PI4-kinase II α Phosphoinositide kinase which mediates formation of PtdIns(4)P at the Golgi best described in Golgi to endosome trafficking.

Class III PI4-kinase III β Phosphoinositide kinase which mediates formation of PtdIns(4)P at the Golgi best described in Golgi to plasma membrane trafficking.

Clathrin Polymerized clathrin molecules form a coat to facilitate vesicle formation.

CtBP1-S/BARS Protein present in the nucleus and cytosol with functions in vesicle fission from membranes.

Double FYVE containing protein 1 (DFCP1) FYVE-domain containing protein involved in autophagosome genesis and found on omegasomes.

Dynamin PH-domain containing protein, which has GTPase activity and is involved in membrane scission for vesicle formation.

Early endosomal antigen 1 (EEA1) FYVE-domain containing protein present at early endosomes and involved in endosomal fusion which interacts with PtdIns(3)P.

Endosomal sorting complexes required for transport complexes 0-III (ESCRT0-III) Multiprotein subunit complexes involved in maturation and ubiquitination of endosomes.

Epidermal growth factor receptor (EGFR) Cell surface receptor for signaling via epidermal growth factor ligands.

Four phosphate adaptor proteins (FAPP) PH-domain containing protein effectors of PtdIns(4)P which also

bind Arf1 and mediate Golgi to plasma membrane secretion.

FYVE and coiled-coil domain containing 1 (FYCO1) FYVE-domain containing protein which regulates autophagosome motility away from the perinuclear region 1.

Golgi localized gamma ear containing ADP-ribosylation factor binding (GGA) Multidomain coat proteins which interact with PtdIns(4)P and coordinate traffic from the Golgi to endosomes.

GTPase activating protein (GAP) Protein which facilitate Rab GTP to GDP transition to promote Rab membrane dissociation.

Guanine nucleotide displacement inhibitor (GDI) Protein which maintains Rab proteins in the cytosol by masking the prenylated tail moiety of the Rab.

Guanine nucleotide exchange factor (GEF) Protein which facilitates Rab GDP to GTP transition to promote Rab recruitment to membrane sites.

Hepatocyte growth regulated tyrosine kinase substrate (Hrs) FYVE-domain containing protein recruited to endosomes and involved in the genesis of multivesicular bodies as part of the ESCRT0 complex.

Homotypic fusion and vacuole sorting complex (HOPS complex) Multisubunit complex containing Vps11, Vps16, Vps18, and Vps33 which coordinates late endosome homotypic fusion.

Inpp5b (75-kDa 5-phosphatase) Phosphoinositide 5-phosphatase with activity against multiple phosphoinositides which forms a complex with a number of endocytic Rab proteins.

Inpp5e Phosphoinositide 5-phosphatase with activity against multiple phosphoinositides which has a role in phagocytosis and when mutated results in ciliopathies.

LC3/GABARAP/GATE16 (Atg8) It remains bound to the maturing autophagosome to form the autophagolysosome.

Lysosomal-associated membrane protein 1 (lamp1) Type-1 transmembrane protein present on lysosomes and late endosomes.

Mammalian target of rapamycin complex 1 (mTORC1) Protein complex which senses nutrient state and acts in growth signaling pathways and regulates autophagy.

MUNC13 PtdIns(4,5)P₂-binding protein involved in plasma membrane exocytosis by priming vesicles and organizing SNARE proteins.

Myotubularin (MTM1) Phosphoinositide 3-phosphatase with roles in muscle function, autophagy, and myotubularin endosomal trafficking.

Myotubularin-related proteins 1-14 (MTMR1-14) Phosphoinositide 3-phosphatases with varying subcellular distributions and roles in endocytic trafficking and autophagy.

Neuronal calcium sensor-1 (NCS-1) Calcium sensor protein associated with vesicle secretion at the Golgi and in neurons.

Oxysterol-binding protein 1 (OSBP1) PH-domain containing protein which binds PtdIns(4)P and Arf1 and regulates sphingomyelin synthesis.

Phaphin2 FYVE-domain containing protein recruited to early endosomes with a role in endosomal fusion.

Phosphatidylinositol (3)-phosphate (PtdIns(3)P) Signaling phosphoinositide present on early and late endosomes with roles in coordinating endosomal trafficking.

Phosphatidylinositol (3,4)-bisphosphate (PtdIns(3,4)P₂) Signaling phosphoinositide present at the plasma membrane and endocytic vesicles with roles in growth factor signaling and emerging role in endocytosis .

Phosphatidylinositol (3,4,5)-trisphosphate (PtdIns(3,4,5)P₃) Signaling phosphoinositide present at low levels in resting cells and rapidly synthesized on stimulation with it roles including growth factor signaling macropinocytosis and phagocytosis.

Phosphatidylinositol (3,5)-bisphosphate (PtdIns(3,5)P₂) Signaling phosphoinositide present on late endosomes with roles in endosomal phosphatidylinositol maturation (3,5)-bisphosphate.

Phosphatidylinositol (4)-phosphate (PtdIns(4)P) Signaling phosphoinositide present at the Golgi with roles in coordinating vesicle phosphatidylinositol trafficking (4)-phosphate.

Phosphatidylinositol (4,5)-bisphosphate (PtdIns(4,5)P₂) Signaling phosphoinositide present at the plasma membrane, Golgi, and nuclear membranes important in many processes including endocytosis, exocytosis, and actin dynamics.

Phosphatase and tensin homolog (PTEN) Phosphoinositide 3-phosphatase with activity against PtdIns(3,4,5)P₃ and regulates cell growth, differentiation, and polarity as a tumor suppressor.

PIKfyve/PIP5K3 Phosphoinositide kinase which converts PtdIns(3)P to PtdIns(3,5)P₂ and PtdIns to PtdIns(5)P.

Rab4 Small GTPase which is recruited to membrane sites when in GTP-bound form and important in recycling endosome function.

Rab5 Small GTPase which is recruited to membrane sites when in GTP-bound form and important in both early and late stages of endocytosis as well as early endosome function.

Rab11 Small GTPase which is recruited to membrane sites when in GTP-bound form and important in recycling endosome function.

Rabenosyn5 FYVE-domain containing protein effector which is recruited to early endosomes and involved in endosome fusion.

Retromer Multisubunit complex containing Vps26p, Vps29p, Vps35p, Vps5p (SNX1 and SNX2), and Vps17p (SNX4 and SNX5) which is involved in endosome to Golgi transport.

SAND-1/Mon1 *Caenorhabditis elegans* protein which directs a switch from early to late endosomes.

SHIP2 Phosphoinositide 5-phosphatase with activity against multiple phosphoinositides and a role in endocytosis, phagocytosis, and insulin signaling.

Soluble NSF attachment protein receptors (SNARES) Family of proteins which mediate vesicle fusion with membranes.

Sorting nexin 3 (SNX3) PX-domain containing protein which acts at endosomes to direct recycling and maturation.

Sorting nexin 4 (SNX4) BAR- and PX-domain containing protein which is involved in the trafficking of transferrin receptor from early endosomes to the recycling compartment.

Sorting nexin 5 (SNX5) BAR- and PX- domain containing protein which induces membrane curvature and regulates macropinocytosis and retrograde trafficking.

Sorting nexin 9 (SNX9) BAR- and PX-domain containing protein which induces membrane curvature and has a role in the late stages of endocytosis.

Synaptojanin-1 Phosphoinositide 5-phosphatase with activity against multiple phosphoinositides and a role in late stages of endocytosis facilitating PtdIns(4,5)P₂ turnover.

Type-I inositol 4-phosphatase

(Inpp4a) Phosphoinositide 4-phosphatase which

degrades PtdIns(3,4)P₂ to generate endosomal PtdIns(3)P and regulates AKT signaling.

Type-II inositol 4-phosphatase

(Inpp4b) Phosphoinositide 4-phosphatase with a role in turnover of PtdIns(3,4)P₂ and endocytosis to endosome transition.

Uncoordinated 51-like kinase (ULK1/ULK2) Serine/threonine protein kinase involved in autophagy induction (Atg1) which forms a complex with mTORC1-Atg13-FIP200 (Atg17)-Atg101 and feeds back to the Class III PI3-kinase complex to increase PtdIns(3)P.

WD-repeat domain containing phosphoinositide interacting proteins (WIPI proteins) WIPI 1/2 (Atg18) and WIPI 3/4 are PtdIns(3)P effectors which can inhibit autophagy (WIPI1) and promote autophagosome maturation (WIPI2b).

Phosphoinositides at the Membrane–Cytosol Interface

Phosphoinositides are glycerophospholipids that contain a diacylglycerol (DAG) lipid membrane-embedded backbone, and a myoinositol head group, that protrudes from membranes into the cytosol. The inositol ring can be phosphorylated at any or all of three possible hydroxyl groups, permitting the generation of seven different possible phosphoinositide species (Figure 1; Balla, 2013). Phosphoinositides constitute only a small component of the total phospholipid within eukaryote cells, however play a significant role in both signaling and trafficking events. The phosphorylation status of the inositol head group allows different phosphoinositides to interact with high specificity with a variety of effector proteins, and it is this selectivity in protein binding that confers the ability of phosphoinositides to act as master organelle traffic controllers (Rusten and Stenmark, 2006; Table 1). The lipid soluble tail localizes phosphoinositides to membrane compartments, and the variably phosphorylated head group lies at the interface between the membrane and the cytosol, a specialized locale containing a complex array of proteins, including enzymes, cytoskeletal structures, and trafficking motors. Contingent on the appearance of a specific phosphoinositide within the cytoplasmic leaflet of an organelle membrane region, there is recruitment of dedicated protein group scaffolds which translate into a plethora of phosphoinositide-dependent functional outcomes.

Organelle Compartments the Spatial Restriction of Phosphoinositide Species and Organelle Identity

A number of generalized membrane compartments can be recognized within the cell, and there is extensive vesicle traffic between these organelles, carrying lipids, membrane-bound proteins such as receptors, and cargo, such as growth factors. There is a distinct subcellular distribution of different

phosphoinositide species, with enrichment at specific organelles, contributing to the identity of that organelle (Figure 2). Membrane trafficking functions include vesicle budding, fission, fusion, and motility. Flow occurs from the plasma membrane, enriched in phosphoinositide 4,5 biphosphate (PtdIns(4,5)P₂), into vesicles, which communicate with the early endosomes, an initial way station for processing. Early endosomes are enriched in phosphoinositide-3-phosphate (PtdIns(3)P), and communicate with the recycling network, by sorting directly back to the plasma membrane, or via a more delayed route via the endocytic recycling compartment (ERC), which exhibits a perinuclear distribution in many cells. Alternatively, vesicles can exit the sorting endosomes in a pathway destined for degradation, and become late endosomes or multivesicular endosomes decorated by PtdIns(3)P and phosphoinositide 3,5 biphosphate (PtdIns(3,5)P₂) to ultimately fuse with acidic and proteolytic lysosomes. Vesicles can also transit from sorting endosomes back to the Golgi in the retrograde pathway, a process which requires PtdIns(3,5)P₂. The endoplasmic reticulum (ER) is the site of protein synthesis, and communicates with both the nucleus and the Golgi compartment, enriched in phosphoinositide 4 phosphate (PtdIns(4)P). Proteins sorted in the Golgi exit the *trans*-Golgi network (TGN) and are sorted via vesicles.

Organelle identity, conferred by the presence of one or more specific phosphoinositide species, is also determined by specific small guanosine 5'-triphosphatase (GTPase) proteins, including the Rab and Arf proteins. These proteins are part of the Ras superfamily, and can exist in an active GTP-bound state, or an inactive guanosine 5'-diphosphatase (GDP)-bound form. Accessory proteins include guanine nucleotide exchange factors (GEFs), that facilitate conversion of a Rab to its GTP-bound, membrane-associated state, and GTPase activating proteins (GAPs) which facilitate conversion back to the GDP-bound state promoting membrane dissociation (Mizuno-Yamasaki *et al.*, 2012). Rabs are chaperoned by guanine nucleotide displacement inhibitors (GDIs), which act to

Figure 1 Phosphoinositide turnover by kinases and phosphatases. Seven different species of phosphoinositides can be formed from the differential phosphorylation of hydroxyl groups on the myoinositol head group of phosphatidylinositol (PtdIns). Different phosphoinositide kinases and phosphatases present at the membrane/cytosolic interface are able to convert one phosphoinositide into another, by the addition or removal of phosphate groups to the inositol head group, respectively. The subcellular distribution, and activation status of these kinases and phosphatases thus dictates the pool of phosphoinositide species present on individual organelles.

maintain Rabs in the cytosol by masking their prenylated tail moiety, but permit cycling into the membrane where they can be stabilized by GEF function into their GTP-bound form (Mizuno-Yamasaki *et al.*, 2012).

Organelle function is dependent on the requirement for the combined presence of both a specific phosphoinositide as well as a Rab or ARF protein to coordinately interact in a process termed coincidence detection, or cooperative binding, with membrane recruited protein effectors (Di Paolo and De Camilli, 2006). The phosphoinositide and small GTPase regulator need to be present and cooperate to enable the

switch to induce the correct functional protein scaffold in order to signal the subsequent membrane trafficking and thereby contribute to essential organelle function.

The regulated turnover of individual phosphoinositides in a controlled fashion is also necessary for coordinated organelle trafficking. The highly specific nature of the interaction between individual phosphoinositides and dedicated binding proteins depends upon the number and configuration of phosphate groups on the myoinositol head group. Thus the addition or removal of a phosphate group, by phosphoinositide kinases or phosphatases, respectively (Figure 1), dictates

Table 1 Phosphoinositide binding domains

Domains		Phosphoinositides bound	Protein examples	References

the ability to recruit protein effectors to a membrane region. Turnover of phosphoinositides via conversion of one species to another by phosphoinositide phosphatases and kinases represents a switch to commence or cease a trafficking or signaling event. In many situations efficient progression of complex trafficking steps requires phosphoinositide inter-conversion of one phosphoinositide species into another (Cullen and Carlton, 2012).

Phosphoinositides in Plasma Membrane Trafficking

Endocytosis

PtdIns(4,5)P₂ plays a major role in plasma membrane trafficking pathways, including endocytosis, the internalization of extracellular components into intracellular membrane-bound vesicles, and exocytosis, the egress of material from intracellular vesicles to the extracellular environment. Endocytosis

occurs by the invagination of membrane buds containing extracellular material, and includes coat protein clathrin-mediated endocytosis, non-coat protein-mediated endocytosis as well as specialized internalization mechanisms such as macropinocytosis and phagocytosis. The critical role PtdIns(4,5)P₂ plays in clathrin-mediated endocytosis illustrates many of the key themes representative of phosphoinositide membrane trafficking (Figure 3). PtdIns(4,5)P₂ is enriched at clathrin-coated pits as well as caveolae (Fujita *et al.*, 2009), and regulates the initial stages of endocytosis, coordinating pit formation. Coated pit initiation requires the PtdIns(4,5)P₂-dependent recruitment of effector proteins to the plasma membrane, including AP2 and AP180 (Godlee and Kaksonen, 2013). The N-terminal regions of AP2 and AP180 contain positively charged domains that interact specifically with PtdIns(4,5)P₂, and AP180 contains a phosphoinositide binding AP180 N-terminal homology (ANTH) domain (Gaidarov and Keen, 1999; Hom *et al.*, 2007). Experimental manipulation to reduce the levels of PtdIns(4,5)P₂ inhibits endocytosis,

Figure 2 Phosphoinositide subcellular distribution to membrane compartments. Different phosphoinositide species are selectively enriched on distinct membrane organelle regions, a phosphoinositide code for organelle identity. There is flow of cargo between the organelles, and turnover of different phosphoinositide species is required for coordinating the orderly function of many membrane processes, as illustrated. Membrane identity is conferred by the individual phosphoinositide species in combination with small GTPases and specific effector proteins (see detailed figures below).

disrupts the recruitment of many of the proteins to the complex endocytosis machinery, and impairs pit invagination (Abe *et al.*, 2008; Sun and Drubin, 2012; Zoncu *et al.*, 2007).

Rab5 is a GTPase protein present at the plasma membrane and on early endosome membranes. *In vitro* Rab5 is required for the early steps of clathrin-coated pit formation, where it is necessary for ligand internalization (McLauchlan *et al.*, 1998). In *Drosophila*, Rab5 is required for endocytosis, and its recruitment to the cortical region under the plasma membrane depends on the presence of PtdIns(4,5)P₂ (Compagnon *et al.*, 2009).

Turnover of PtdIns(4,5)P₂ is required for normal endocytosis progression. Cells with increased PtdIns(4,5)P₂ levels have enlarged pits (Antonescu *et al.*, 2011; Sun and Drubin, 2012). Inositol polyphosphate 5-phosphatases, such as synaptojanin-1 are recruited to clathrin-coated pits, and promote maturation of pits, in part via the degradation of PtdIns(4,5)P₂. This leads to a phosphoinositide switch, whereby PtdIns(4,5)P₂ is converted to PtdIns(4)P via 5-phosphatase activity and PtdIns(3,4)P₂ is formed at clathrin-coated pits by the activity of Class II PI3-kinase C2α (PIK3C2A), as recently suggested by one report (Posor *et al.*, 2013). This switch is important for the normal maturation of clathrin-coated pits and is required for the recruitment of the effector sorting nexin 9 (SNX9) (Posor *et al.*, 2013). Fission to form an intracellular vesicle is mediated by the PtdIns(4,5)P₂-effector dynamin which contains a PH domain (Balla, 2013). In neurons, synaptojanin-1 is required for efficient endocytosis and re-availability of synaptic vesicles for neurotransmission, postulated to be a result of the need for removal of PtdIns(4,5)P₂ to allow the uncoating of internalized vesicles (Mani *et al.*, 2007). Synaptojanin-1 knockout mice exhibit an accumulation of clathrin-coated vesicles (Hayashi *et al.*, 2008). Endophilin is a BAR domain containing protein which recruits synaptojanin-1 to clathrin-coated pits, and thus facilitates PtdIns(4,5)P₂ degradation prior to dynamin-mediated fission (Milosevic *et al.*, 2011). Additionally, the small GTPase Rab5, and with its activating protein (GEF) Rabex 5 are recruited to clathrin-coated pits, to promote the exclusion of PtdIns(4,5)P₂ from the formed vesicle and vesicle uncoating (Compagnon *et al.*, 2009; Semerdjieva *et al.*, 2008). Thus endocytosis

requires both the enrichment and localization of PtdIns(4,5)P₂ and its progression involves PtdIns(4,5)P₂ regulated turnover.

In contrast to the above events, in some stimulated forms of endocytosis there is a prominent regulatory role for phosphoinositide 3,4,5 trisphosphate PtdIns(3,4,5)P₃, the product of Class I PI3-kinase action on PtdIns(4,5)P₂. Endocytosis of the G-protein coupled β-adrenergic receptor is important for down-regulation of the adrenergic signal and requires PtdIns(3,4,5)P₃ (Naga Prasad *et al.*, 2002). Agonist occupation of the β-adrenergic receptor results in the recruitment of the Class I PI3-kinase via β-adrenergic receptor kinase, which enhances AP2 recruitment and clathrin-coated pit formation (Naga Prasad *et al.*, 2002).

Phagocytosis, the engulfment of large particles such as apoptotic cells or microorganisms and macropinocytosis, the internalization of extracellular fluid, are specialized forms of receptor-mediated endocytosis (Figure 4). Following receptor stimulation, extensive changes in the actin cytoskeleton occur, to produce pseudopods, in the case of phagocytosis, and ruffling, in the case of macropinocytosis. Both of these processes are characterized by the appearance of PtdIns(3,4,5)P₃ in the membrane of pseudopods and late-stage ruffles (Swanson, 2008). PtdIns(3,4,5)P₃ binds WAVE, an actin nucleation promoting factor, and signals via the Rho GTPases Rac and Cdc42 to contribute to the dramatic actin dynamics observed during phagocytosis (Padrick and Rosen, 2010). Phosphoinositide 5-phosphatases can degrade PtdIns(3,4,5)P₃ to form PtdIns(3,4)P₂, at phagocytic cups and macropinosomes (Horan *et al.*, 2007; Maekawa *et al.*, 2014). The SNX5 may be recruited by PtdIns(3,4)P₂ at the macropinosome, where it regulates the number and size of macropinosomes and tubules (Lim *et al.*, 2012). Turnover of PtdIns(3,4)P₂ is also essential for the completion of macropinocytosis, with sequential actions of the 4-phosphatase Inpp4b, and the 3-phosphatases MTMR6 and MTMR9 controlling the phosphoinositide flux in *Caenorhabditis elegans* macropinocytosis (Maekawa *et al.*, 2014).

However, further work is needed to establish a clear role for PtdIns(3,4,5)P₃ in the regulation of other clathrin- and non-clathrin-mediated endocytocytic events. Knockdown of

Figure 3 Endocytic steps and phosphoinositide engagement. PtdIns(4,5)P₂ and PtdIns(3,4)P₂ are sequentially involved in endocytosis. Shown is a schematic for clathrin-mediated endocytosis. Multiple adaptor and accessory proteins assemble at the site of the receptor, relying on combined coincidence detection to overcome otherwise weak interactions. AP2 and AP180 binding require PtdIns(4,5)P₂ present in membrane patches, essential for the initiation of the clathrin-coated pit. This results in pit invagination and progression of clathrin-coat formation. Later stages of endocytosis require turnover of PtdIns(4,5)P₂, mediated by the sequential recruitment of the 5-phosphatase synaptojanin-1 (SYNJ1), and then clathrin-dependent PI3KC2α to generate PtdIns(3,4)P₂. Rab5 is also present on clathrin-coated vesicles and may also contribute to loss of PtdIns(4,5)P₂. Membrane curvature and PtdIns(3,4)P₂ may recruit the PX/BAR domain containing sorting nexin 9 (SNX9) and possibly SNX18 and subsequently dynamin (DNM1), an additional PtdIns(4,5)P₂ effector, to mediate fission of the clathrin-coated vesicle. This then undergoes uncoating prior to entering the early endosomal system.

the inositol polyphosphate Type 1 α 4-phosphatase inhibits Rab5-dependent transferrin uptake (Shin *et al.*, 2005). SHIP2 5-phosphatase, which has a preference for PtdIns(3,4,5)P₃ as a substrate, is recruited to clathrin-coated pits to negatively regulate their growth, however SHIP2 also has activity against PtdIns(4,5)P₂ (Nakatsu *et al.*, 2010). Experimental manipulation to increase plasma membrane PtdIns(3,4,5)P₃ levels by directly activating Class I PI3-kinase results in shorter clathrin-coated pit lifetimes, either a direct result of PtdIns(3,4,5)P₃ signals, or possibly representing the impact of turnover of PtdIns(4,5)P₂ (Nakatsu *et al.*, 2010). However, overexpression of PTEN, which results in reduced plasma membrane PtdIns(3,4,5)P₃, has no effect on endocytosis of transferrin (Posor *et al.*, 2013).

Exocytosis

During exocytosis, vesicles mobilize to the plasma membrane, where they fuse to intermix and deliver their cargo to the extracellular space. Exocytosis requires the coordination of motor machinery such as myosins and kinesins, the cytoskeletal network including actin microtubules together with membrane fusion apparatus including SNAREs. Exocytosis has been studied extensively in neuroendocrine cells, specifically exocytosis of dense core vesicles, which is calcium dependent, and to a lesser degree in neuronal synaptic vesicle exocytosis, as well as constitutive exocytosis from the Golgi (Martin, 2012). Examples of specialized exocytosis occur in neurotransmitter transmission and leukocyte cytotoxicity. PtdIns(4,5)P₂ localizes to sites of exocytosis (James *et al.*, 2008). Increasing or decreasing PtdIns(4,5)P₂ signals results in corresponding increased or decreased exocytosis, respectively (Martin, 2012). Effector proteins which bind PtdIns(4,5)P₂ include CAPS and MUNC13 (Kabachinski *et al.*, 2014). Paradoxically, it has been suggested that PtdIns(4,5)P₂ alone can inhibit vesicle fusion, until additional factors such as the effector CAPS are present (James *et al.*, 2008). CAPS requires PtdIns(4,5)P₂ for its activity

in priming, the process by which vesicles docked at a recipient membrane site become fusion ready (Kabachinski *et al.*, 2014). MUNC13 is recruited to vesicles by PtdIns(4,5)P₂ at the plasma membrane in a calcium-dependent manner. Under high agonist stimulation conditions, phospholipase C η 2 hydrolyzes PtdIns(4,5)P₂ into DAG which itself can regulate fusion (Kabachinski *et al.*, 2014). PtdIns(4,5)P₂ also reorganizes actin to mobilize secretory vesicles for exocytosis (Wen *et al.*, 2011). In yeast, PtdIns(4,5)P₂ is required for secretion from the Golgi to the plasma membrane. PtdIns(4,5)P₂ interacts to recruit components of the exocyst, a multisubunit complex that facilitates the recruitment and fusion of vesicles with the plasma membrane (Martin, 2012).

There is an additional role for PtdIns(3)P in specialized exocytosis. Class II PI3-kinase-derived PtdIns(3)P is required for the priming of large dense core vesicles for exocytosis in neurons (Meunier *et al.*, 2005). This is negatively regulated by the turnover of PtdIns(3)P via the PIKfyve kinase, converting PtdIns(3)P to PtdIns(3,5)P₂ (Osborne *et al.*, 2008). Class II PI3-kinase also regulates insulin secretion from granules in pancreatic beta cells, and insulin stimulated GLUT4 vesicle exocytosis in skeletal muscle (Dominguez *et al.*, 2011; Falasca and Maffucci, 2007).

Phosphoinositides in the Endosomal Compartment – Early Endosomes, Recycling Endosomes, and Late Endosomes

Endocytosed cargo within their membrane vesicles become part of a way station known as the early, or sorting endosomal compartment (Figure 5). Early endosomes in many cells are located in the cell periphery, exhibit a characteristic tubule-vesicular morphology, and represent a site for the direction of vesicle traffic via a number of routes. In the recycling pathway, cargo and membrane, can branch off in tubules from sorting endosomes, to either recycle directly to the plasma membrane,

Figure 4 Phosphoinositide pathway in phagocytosis. Phagocytosis is an example of a specialized form of endocytosis in which PtdIns(3,4,5)P₃ has a prominent role. Shown is a schematic depicting Fc γ R-mediated phagocytosis. Antibody opsonised particles engage multiple Fc γ Rs via their Fc domains, clustering the receptors and initiating signaling via the Src tyrosine kinases which activates Fc γ Rs, to recruit Syk and Class I PI3-kinase. PtdIns(4,5)P₂ present in the plasma membrane is enriched at phagocytic cups, together with PIP5K α . Class I PI3-kinase generates PtdIns(3,4,5)P₃ from PtdIns(4,5)P₂ at the phagocytic cup, and these phosphoinositides contribute to the dramatic changes in actin polymerization necessary for the advancement of pseudopods, via interactions with actin nucleating factors such as WAVE, Cdc42, and Rac1. Turnover of PtdIns(4,5)P₂ occurs via phospholipase C δ (PLC δ) and Class I PI3-kinase (SHIP2) and is required for normal actin remodeling to complete phagocytosis. Additionally, PtdIns(3,4,5)P₃ is converted to PtdIns(3,4)P₂ at the phagocytic cup by the action of 5-phosphatases such as Inpp5e. Pseudopod membrane grows by the recruitment of intracellular membrane sources, such as Rab11- and Rab5-positive endosomes.

or for storage in the ERC. Alternatively, within a 5–10 min time point, early endosomes can develop a progressively lower pH, together with the acquisition of a hydrolytic environment in a process termed maturation (Cullen and Carlton, 2012). During maturation internalized cargo is transported in an endosome which converts from an early to a late endosome, a degradative organelle which fuses with lysosomes. Additionally, vesicular traffic can leave the early and late endosomal compartment via the retrograde pathway, for transport of membrane back to the TGN (Cullen and Carlton, 2012).

The early endosome is marked by the monophosphorylated phosphoinositide PtdIns(3)P, Rab5, and the endosomal fusion protein EEA1 (Zoncu *et al.*, 2009). Immediately following endocytosis, some cargos such as epidermal growth factor and nerve growth factor can enter a precursor to early endosomes, which is Rab5-positive, and is labeled by the presence of the membrane adaptor complex APPL, but the absence of EEA1 (Compagnon *et al.*, 2009; Zoncu *et al.*, 2009). The recruitment of PtdIns(3)P is required for the transition from the APPL-positive precursor endosome to APPL-negative, EEA1 positive early endosome (Zoncu *et al.*, 2009). Rab5 is itself involved in the formation of PtdIns(3)P, by recruiting the Class III PI3-kinase which generates PtdIns(3)P from PtdIns. The Class III PI3-kinase subunit p150/Vps15 interacts with GTP-bound Rab5 via HEAT and WD40 domains and localizes to early endosomes (Murray *et al.*, 2002). Early endosomal PtdIns(3)P may also be formed indirectly by the Class I PI3-kinase acting in conjunction with phosphoinositide phosphatases in a sequential cascade on the inner leaflet of the plasma membrane. Class I PI3-kinase catalyzes the formation of PtdIns(3,4,5)P₃ from PtdIns(4,5)P₂ at the plasma membrane, and the degradation of PtdIns(3,4,5)P₃ is in part accomplished by the recruitment of phosphoinositide 5-phosphatases to generate PtdIns(3,4)P₂, and then 4-phosphatases to generate PtdIns(3)P (Shin *et al.*, 2005). Interestingly, Rab5 interacts with the Class I PI3-kinase as well as the 5-phosphatase, Inpp5b, and 4-phosphatase, Inpp4a. It has been estimated that up to 30% of endosomal PtdIns(3)P may be formed in a Rab5-dependent cascade producing a phosphoinositide gradient from PtdIns(3,4,5)P₃ to PtdIns(3)P between the plasma membrane and the early endosome (Shin *et al.*, 2005). In some specialized circumstances, PtdIns(3)P is generated by Class II PI3-kinase on endosomes, including in *Drosophila* hemocytes and at pericentriolar endosomes at the base of primary cilia in mouse embryonic fibroblasts (Franco *et al.*, 2014; Velichkova *et al.*, 2010).

PtdIns(3)P on early endosomal membranes recruits effector proteins containing FYVE and PX domains (Balla, 2013). The FYVE domain is a zinc binding finger, and a large number of proteins have been identified containing this domain (Kutateladze, 2006). In most contexts a single FYVE domain is insufficient for high-affinity PtdIns(3)P binding alone. Many FYVE domain containing proteins have been identified, however, their regulation and function has only begun to be characterized. Of these, EEA1 is the best studied, but whether this is a model for the function of the other FYVE domain containing proteins remains to be shown. Early endosome recruitment of EEA1 is accomplished by FYVE domain interaction with PtdIns(3)P, together with EEA1 dimer formation between EEA1 coiled-coil domains (Kutateladze,

2006). Additionally, EEA1 also binds Rab5 directly by a separate domain adjacent to the FYVE domain, an example of the importance of cooperative binding of an effector to both a Rab GTPase and a phosphoinositide. In the case of other FYVE domain containing proteins, oligomerization (as for early endosomal Hrs and SARA) and tandem FYVE domains (as in the case of the ER and Golgi localized double FYVE containing protein 1 (DFCP1)), have been described (Kutateladze, 2006). The SNX proteins are an example of early endosomal recruitment via PX domains, with some SNXs additionally containing a curved membrane sensing BAR domain, that targets proteins to high-curvature subdomains of the early endosome. This facilitates the pinching off of tubular membrane extensions and fission (Cullen and Carlton, 2012). The SNXs direct cargo and receptors out of the early endosome into the recycling endosomal compartment or back to the secretory pathway via retrograde recycling (Cullen and Carlton, 2012). An example of this is SNX4, present on early and recycling endosomes, which facilitates the channeling of membrane-embedded transferrin and its receptor away from the degradative pathway and into the recycling pathway by virtue of regulating egress of tubular membranes with a higher surface area to volume ratio (Traer *et al.*, 2007).

Sequential transport from early to late endosomes in the degradative pathway involves the development of multi-vesicular bodies, with intraluminal vesicles that sequester ubiquitinated cargo for degradation away from the recycling process. PtdIns(3)P is present on intraluminal vesicles (Cullen and Carlton, 2012). Turnover of PtdIns(3)P can occur via conversion to PtdIns(3,5)P₂ by the PIKfyve complex, and inhibition of PIKfyve produces dramatic endosomal morphologic changes (De Lartigue *et al.*, 2009). PtdIns(3,5)P₂ is important for retrograde trafficking, epidermal growth factor receptor (EGFR) degradation and autophagy. The recent development of a PtdIns(3,5)P₂ probe has demonstrated that PtdIns(3,5)P₂ is predominantly present on Lamp1-positive late endosomes, where it is dynamically enriched immediately preceding late endosomal fusion events (Li *et al.*, 2013).

Intraluminal vesicle development is accomplished by four phosphoinositide interacting complexes, ESCRT 0-III (Cullen and Carlton, 2012). Hrs is a FYVE domain containing protein and a component of ESCRT-0, and ESCRT I-II may bind PtdIns(3)P by other mechanisms (Cullen and Carlton, 2012). The ESCRT-II subunit Vps36 has been reported to bind PtdIns(3)P, and its mammalian homologue binds PtdIns(3,4,5)P₃ (Slagsvold *et al.*, 2005; Teo *et al.*, 2006). ESCRT-III is responsible for fission and may bind PtdIns(3,5)P₂ (Cullen and Carlton, 2012). Additionally SNX3 may represent an ESCRT independent means for forming a multivesicular body (Cullen and Carlton, 2012). In *C. elegans*, SAND-1/Mon1 has been proposed as the switch in early to late endosome transition. SAND-1/Mon1 is recruited to early endosomes, possibly by binding to PtdIns(3)P, and also complexes with Rabex5, a GEF for Rab5, to displace this GEF from early endosomes (Poteryaev *et al.*, 2010). SAND-1/Mon1 and Rab5 both interact with the HOPS complex, which possesses GEF activity for Rab7. Early endosomes thus lose Rab5 and acquire Rab7 in the maturation process of the degradative pathway (Rink *et al.*, 2005).

The normal maturation of endosomes in the degradative pathway requires the turnover of PtdIns(3)P. The PIKfyve

Figure 5 Endosomal phosphoinositide compartment maturation. The early endosome represents a way station for endocytosed vesicles, characterized by PtdIns(3)P. Rab5 recruits the Class I PI3-kinase, representing the source of the majority of early endosomal PtdIns(3)P. The PtdIns(3)P effector EEA1 is recruited and retained on early endosomes by coincidence detection of PtdIns(3)P interaction with its FYVE domain, and binding to Rab5. EEA1 and other FYVE domain containing effectors such as Phafin2 and rabenosyn 5 facilitate fusion between endosomes. Egress from the early endosome can occur via tubular branching for recycling and retrograde trafficking, mediated by the SNXs, which interact with PtdIns(3)P through their PX domains, in coincidence detection with BAR domain detection of membrane curvature. Receptors such as the transferrin receptor bound to transferrin can recycle directly to the plasma membrane, mediated by Rab4, or indirectly via a storage reservoir termed the ERC, mediated by Rab11. During retrograde trafficking, vesicles traffic from endosomes to the Golgi network, mediated by the retromer complex of SNXs which interact with PtdIns(3)P via PX domains. Turnover of PtdIns(3)P into PtdIns(3,5)P₂ is necessary for retrograde trafficking, and is impaired by pharmacologic inhibition of PIKfyve. Early endosomes can also mature into late endosomes for lysosomal fusion. Hrs is FYVE domain containing effector protein which is part of the ESCRT0 complex and directs the formation of internal vesicles. PtdIns(3)P also recruits SAND-1/Mon1 which permits the switch from Rab5 to Rab7 and the recruitment of the HOPS complex for the progression of endosomal maturation. The late endosome is positive for PtdIns(3,5)P₂. The myotubularins MTM1 and MTMR4 (contains a FYVE domain) have been identified at early endosomes and MTMR2 at late endosomes where they regulate PtdIns(3)P turnover.

complex can convert PtdIns(3)P to PtdIns(3,5)P₂. Additionally, myotubularins MTM1, MTMR2, and MTMR4 localize to early and late endosomes, and represent a means of degradation of both PtdIns(3)P and PtdIns(3,5)P₂, and mechanism for generating PtdIns(5)P (Davies *et al.*, 2012). The importance of a normal flux in endosomal PtdIns(3)P is highlighted by the observations that both increased as well as decreased or dominant negative PtdIns(3)P 3-phosphatase activity retards the degradation of EGFR (Lorenzo *et al.*, 2006; Pedersen *et al.*, 2012).

Phosphoinositides in Golgi Trafficking

The Golgi apparatus is a prominent network of flat membrane cisternae responsible for the modification and sorting of proteins and lipids. The *cis*-Golgi receives proteins and lipids from the ER, and after passage with modification through

the Golgi cisternae, vesicle carriers can exit from the TGN. Anterograde vesicular sorting occurs to the cell surface, and also to the endosomal network via clathrin-coated protein vesicles. Retrograde sorting back to the ER is via coated protein I (COPI) vesicles. The predominant signaling phosphoinositide at the Golgi is PtdIns(4)P, with small amounts of other phosphoinositides, including PtdIns(4,5)P₂ and PtdIns(3,4,5)P₃ also present (D'angelo *et al.*, 2012; Figure 6). PtdIns(4)P at the Golgi was initially thought to be a precursor for PtdIns(4,5)P₂ until subsequent studies demonstrated PtdIns(4)P to be essential for Golgi secretion in yeast. More recently, growing numbers of PtdIns(4)P-specific effectors have been shown to regulate Golgi sorting (D'angelo *et al.*, 2012). In yeast, one Class III PI4-kinase (PIK1) is responsible for Golgi PtdIns(4)P production. In mammals, there are four different phosphoinositide 4-kinases which localize to the Golgi, however the Class III (wortmannin-sensitive) PI4-kinase III β and the Class II (wortmannin-insensitive) PI4-kinase II α are the

predominant sources of PtdIns(4)P synthesis. Disruption of PtdIns(4)P signaling has dramatic effects on TGN function (D'angelo *et al.*, 2012).

PI4-kinase III β is present at the Golgi, endosomes, exocytic vesicles, lysosomes, and in the nucleus. Its most well-established role is to facilitate vesicle export to the plasma membrane (D'angelo *et al.*, 2012; Sridhar *et al.*, 2013). PI4-Kinase III β is recruited to the Golgi by the small GTPase Arf1, and is required for normal secretory function (Haynes *et al.*, 2005). The calcium sensor NCS-1 is also present at the TGN and recruits and activates PI4-Kinase III β , however, the complex of PI4-Kinase III β , Arf1 and NCS-1 is inhibitory to PI4-Kinase III β function (Haynes *et al.*, 2005). PI4-Kinase III β activity requires phosphorylation by the serine/threonine kinases PKD1 and 2 which are recruited to the Golgi by diacylglycerol, and increase transport from the TGN to the plasma membrane (Hausser *et al.*, 2005). PI4-Kinase III β kinase activity is stabilized by interaction of 14-3-3 protein dimers, which form scaffolds with CtBS/BARS and PI4-Kinase III β , essential for the budding of tubular domains from the TGN (Hausser *et al.*, 2005; Valente *et al.*, 2012). PtdIns(4)P and Arf1 can participate in coincidence detection of PH domain containing effectors. The PI4-Kinase III β pool of PtdIns(4)P mediates TGN to cell surface sorting of vesicles via FAPP1 and FAPP2, which are recruited to the TGN by interaction of their PH domains with PtdIns(4)P. The correct localization of FAPP1/FAPP2 requires Arf1 in addition to PtdIns(4)P, and inhibition of Arf1 activation prevents FAPP recruitment (Godi *et al.*, 2004). FAPP2 is also involved in glycosphingolipid biosynthesis, and initially associates with the *cis*-Golgi, where it binds glucosylceramide with subsequent increase in its affinity for PtdIns(4)P, resulting in relocation of FAPP2 to the TGN and delivery of glucosylceramide to this site (D'angelo *et al.*, 2013). During sphingomyelin synthesis, ceramide is transferred from the ER to the Golgi, and PtdIns(4)P is required at this early stage to recruit the PH domain containing CERT protein (Toth *et al.*, 2006). Oxysterol-binding protein 1 (OSBP) also regulates sphingomyelin synthesis, contains a PH domain, and binds PtdIns(4)P and Arf1 at the Golgi (Levine and Munro, 2002).

PI4-kinase II α is present on Golgi and endosomal membranes and regulates Golgi to endosome sorting (D'angelo *et al.*, 2012). Unlike PI4-Kinase III β , PI4-kinase II α recruitment to the Golgi is Arf1-independent. Cholesterol regulates PI4-kinase II α activity, possibly by altering its membrane mobility and therefore restricting PtdIns(4)P production to microdomains (Minogue *et al.*, 2010). Additionally, OSBP is involved in positive feedback to activate PI4-kinase II α , for recruitment of the PtdIns(4)P effector, CERT, to the TGN during sphingomyelin synthesis (Banerji *et al.*, 2010). Transfer from the TGN to endosomes/lysosomes occurs via clathrin-coated vesicles. PtdIns(4)P formed predominantly by PI4-kinase II α is required for the recruitment of the phosphoinositide effectors AP1, GGA, and Epsins to the TGN, a process that requires coincidence detection with Arf1 (Wang *et al.*, 2003, 2007).

PtdIns(4)P also regulates anterograde transport from the ER to the early Golgi, via COPII coated vesicles, where it acts at the SNARE-dependent fusion stage of vesicles with the Golgi (Lorente-Rodriguez and Barlowe, 2011). PtdIns(4)P

additionally regulates Golgi morphology, through interaction with positively charged domains on the PtdIns(4)P effectors Golgi phosphoprotein 3 (GOLPH3) and Golgi phosphoprotein 3-like (GOLPH3L) (Dippold *et al.*, 2009; Ng *et al.*, 2013). These proteins exert opposing effects on the shape of the Golgi (Ng *et al.*, 2013). GOLPH3 links PtdIns(4)P to the actin cytoskeleton via the myosin Myo18, maintaining a compressed Golgi ribbon structure and contributing to vesicle budding (Dippold *et al.*, 2009). The yeast homologue of GOLPH3 is Vps74p, and functions in retrograde traffic of COPI vesicles from the medial Golgi. Additionally, Vps74p contributes to PtdIns(4)P turnover. Vps74p binds the phosphoinositide phosphatase, SAC1, which degrades PtdIns(4)P to form PtdIns and terminate PtdIns(4)P signaling at the early Golgi apparatus to maintain cisternal identity (Cai *et al.*, 2014). In yeast, turnover of PtdIns(4)P has also been demonstrated in the anterograde pathway. Recruitment of the GEF Sec2p occurs via coincidence detection between Ypt32p (mammalian homologue Rab11b) and PtdIns(4)P, resulting in the activation of the Rab GTPase Sec4p (mammalian homologue Rab8). However, as vesicles reach secretory sites, PtdIns(4)P signals decline, and this switch dissociates Sec2p from Ypt32p, allowing Sec2p to interact with Sec15p, a component of the exocyst required for vesicle tethering for exocytosis (Mizuno-Yamasaki *et al.*, 2012).

Retrograde Trafficking from Endosomes to Golgi

Retrograde transport is important for the retrieval of proteins and lipids back to the Golgi apparatus. Retrograde trafficking of cargo such as the mannose-6-phosphate receptor, which delivers hydrolases to endosomes before being recycled, occurs via the multimeric complex retromer (Bonifacino and Hurley, 2008). Additionally, there are retromer independent retrograde pathways, such as the transport of the plant toxin ricin (Cullen and Carlton, 2012). The yeast multimeric retromer complex consists of the trimer Vps26p–Vps29p–Vps35p and also Vps5p and Vps17p (Cullen and Carlton, 2012). In the mammalian complex there are two Vps5p homologues, SNX1 and SNX2 and two Vps17p homologues, SNX5 and SNX6 (Cullen and Carlton, 2012). Retrograde transport is achieved through tubule based sorting, whereby cargo is enriched in forming tubules which can then undergo fission for trafficking (Van Weering *et al.*, 2012). A number of SNX proteins undergo coincidence detection via their phosphoinositide binding PX domain, and a membrane curvature-sensing BAR domain, targeted to the highly curved tubulovesicular endosomes where they are involved tubule formation (Van Weering *et al.*, 2012). The phosphoinositides involved in retrograde trafficking include PtdIns(3)P and PtdIns(3,5)P₂, however, this remains an emerging field. In yeast, Vps34, the Class III PI3-kinase has a direct role in the regulation of retromer function (Burda *et al.*, 2002). SNX1 and SNX2 localize to early endosomes, the site of PtdIns(3)P enrichment, and bind PtdIns(3)P and PtdIns(3,5)P₂ (Carlton *et al.*, 2005; Cozier *et al.*, 2002). SNX3 a non-BAR domain containing SNX binds PtdIns(3)P and interacts with retromer in an alternative pathway for the recycling of Wntless (Harterink *et al.*, 2011). The PIKfyve 5-kinase catalyzes the conversion of PtdIns(3)P to PtdIns(3,5)P₂,

Figure 6 Golgi trafficking regulation by phosphoinositides. PtdIns(4)P is important in Golgi membrane trafficking. PI4KII α mediates the formation of PtdIns(4)P at the TGN, best described in the formation of coated vesicles for Golgi to endosome trafficking. Coincidence detection occurs between PtdIns(4)P and Arf1 for the recruitment of effector proteins such as AP1, GGAs, and EpsinR for the formation of clathrin-coated endosomes. PI4KIII β is also recruited to the TGN mediated via Arf1 in combination with NCS and Rab11, best described for the formation of vesicles destined for exocytosis at the plasma membrane. PtdIns(4)P and Arf1 recruit the PH domain containing effector FAPP2, involved in the initiation of vesicle budding. Positive feedback of PI4KIII β to make more PtdIns(4)P, stabilized by a scaffold of PKD, 14-3-3 proteins, Rab11, and CtBp/BARS contributes to the fission of vesicles from the TGN.

and is necessary for normal retromer function, suggesting that turnover of PtdIns(3)P into PtdIns(3,5)P₂ is an important requirement for retrograde trafficking (Rutherford *et al.*, 2006). Consistent with this, the myotubularin 3-phosphatases,

MTM-6 and MTM-9, which degrade PtdIns(3)P and PtdIns(3,5)P₂ are required for Wnt signaling via retromer in *C. elegans* (Silhankova *et al.*, 2010). The tubulation function of SNX1 is timed to Rab conversion in endosome maturation,

and is most prominently observed on endosomes transitioning from Rab5 (early)-positive to Rab7 (late)-positive (Van Weering *et al.*, 2012). Additionally, coincidence detection occurs between retromer, SNX3 and Rab7 on endosomes (Lorenowicz *et al.*, 2014).

Phosphoinositides in the Regulation of Autophagy

Macroautophagy (hereafter called autophagy) is a conserved membrane-regulated degradative mechanism which functions in cell homeostasis and under conditions of stress, such as starvation. Autophagy is implicated in disease processes such as neurodegeneration, cancer, and heart disease. During autophagy, cytosolic contents are sequestered within a membrane-bound compartment, and delivered to the lysosome (Figure 7). Autophagy permits the regeneration of damaged organelles, such as mitochondria and the ER, the regulation of lipid metabolism, the clearance of protein aggregates from the cell and the destruction of intracellular microorganisms (Choi *et al.*, 2013; Deretic, 2006). In yeast, 37 autophagy-related proteins (Atg proteins) have been described (Lamb *et al.*, 2013). The direction of autophagic signals to the membrane source is termed initiation, and autophagy can be stimulated by amino acid deprivation. Nucleation is the creation of the pre-autophagosomal structure, which subsequently leads to the formation of an isolation membrane which sequesters cytosolic content and fuses to surround that content within a double membrane autophagosome. The autophagosome then undergoes a maturation process to fuse with the vacuole, the yeast equivalent of the mammalian lysosomes (Lamb *et al.*, 2013; Mizushima, 2007).

Phosphoinositides are able to influence autophagy at different steps. Growth factor or insulin stimulated production of PtdIns(3,4,5)P₃ at the plasma membrane catalyzed by the Class I PI3-kinase negatively regulates autophagy (Devereaux *et al.*, 2013). Plasma membrane PtdIns(3,4,5)P₃ recruits and activates Akt, which contributes to a complex signaling cascade which results in mTORC1 activation (Devereaux *et al.*, 2013). mTORC1 inhibits autophagy at the initiation stage by forming a complex with ULK1/ULK2 (mammalian homolog of Atg1), Atg13, and FIP200 (postulated homolog of Atg17) under nutrient rich conditions. mTORC1 is excluded from the complex upon starvation (Hosokawa *et al.*, 2009). When not associated with mTORC1, ULK1/2 and Atg13 are dephosphorylated and in complex with Atg17 translocate to membranes to initiate autophagy (Hosokawa *et al.*, 2009). Intriguingly, the class I PI3-kinase subunit p110 β is a positive regulator of autophagy, independent of its PI3-kinase activity/mTORC1 influence, and forms a complex with the Class III PI3-kinase (Vps34)–Beclin 1–Vps15–Atg14L, involved in the initiation of autophagy (see below) (Dou *et al.*, 2010).

PtdIns(3)P is a critical signal to stimulate autophagy. The main source of PtdIns(3)P in autophagy is the Class III PI3-kinase (Vps34), with contribution from Class II PI3-kinase (Devereaux *et al.*, 2013). Initiation and nucleation require both the translocation of the ULK1 complex (ULK1–Atg13–FIP200–Atg101) to a membrane source, as well as the creation of PtdIns(3)P by the complex of Vps34–Beclin1 (homolog of Atg6)–Vps15–Atg14L (Lamb *et al.*, 2013). PtdIns(3)P

facilitates the recruitment of the ULK1 complex to autophagic puncta, and the ULK1 complex itself feeds back to increase the formation of PtdIns(3)P by activating the PI3-kinase complex (Karanasios *et al.*, 2013; Russell *et al.*, 2013). The early autophagosomal membrane in some settings is termed an omegasome, connected to the ER, marked by PtdIns(3)P and the FYVE domain containing PtdIns(3)P effector DFCEP1. However, the exact function of DFCEP1 in autophagy remains unclear (Lamb *et al.*, 2013). The WD-repeat domain containing phosphoinositide interacting proteins (WIPI) 1/2 (yeast homologue Atg18) and 3/4 proteins are additional PtdIns(3)P effectors which contain WD-repeat PROPPIN domains important in autophagosome formation. WIPI1 may have an inhibitory role in autophagy (Polson *et al.*, 2010). WIPI2b contributes to the maturation of the autophagosome, by directly binding Atg16L1 on omegasomes, which is responsible for the recruitment of the Atg12–Atg5–Atg16L complex to autophagosomes (Dooley *et al.*, 2014). This complex has E3 ubiquitin ligase-like function that promotes the lipidation of the autophagy Atg8 homologues microtubule associated protein light chain 3 (LC3), GABARAP, and GATE16 (Lamb *et al.*, 2013). The *C. elegans* protein EPG-6 is the homologue of WIPI4, and is important in directing autophagosomal membrane size, possibly via forming a complex with Atg2 and regulating the membrane delivery function of the transmembrane protein Atg9 (Lu *et al.*, 2011). Another PtdIns(3)P effector which coordinates membrane delivery to the autophagosome via Atg9 is UV radiation resistance-associated gene protein (UVRAG), which binds a pool of PtdIns(3)P at ER membrane regions (He *et al.*, 2013). Under basal conditions, UVRAG coordinates *cis*-Golgi to ER retrograde trafficking, but upon stimulation of autophagy UVRAG is part of an alternative PI3-kinase complex which activates Beclin1 and Vps34 (He *et al.*, 2013). Additionally, the PH domain containing effector tectonin β -propeller repeat containing 1 TECPR1 contributes to the recruitment of Atg5, and one report suggests it binds PtdIns(3)P and is required for autophagosome–lysosome fusion (Chen *et al.*, 2012).

Cytosolic LC3-I (Atg8 homologue) is recruited to autophagosomes and undergoes lipidation to become LC3-II via the Atg12–Atg5–Atg16L complex. During autophagosome maturation, most of the other Atg proteins dissociate from the membrane, but lipidated LC3-II remains bound and traverses to the autophagolysosome. LC3 is the proposed receptor for p62, which has a ubiquitin-binding domain and may mediate recruitment of ubiquitin containing proteins to the autophagosome membrane (Mizushima, 2007). FYVE and coiled-coil domain containing 1 (FYCO1) is a recently described FYVE domain containing protein which regulates autophagosome motility away from the perinuclear region by directing microtubule plus end motility through interactions with Rab7 and LC3 (Pankiv *et al.*, 2010). The autophagosome matures by fusion with endosomes and lysosomes (Mizushima, 2007). Early evidence suggests that PtdIns(3,5)P₂ may also regulate autophagy, although the site of PtdIns(3,5)P₂ action is unclear (De Lartigue *et al.*, 2009). Inhibition of the 5-kinase PIKfyve, responsible for turnover of PtdIns(3)P into PtdIns(3,5)P₂, dysregulates autophagy, possibly by preventing autophagosome consumption by lysosomes (De Lartigue *et al.*, 2009; Martin *et al.*, 2013). Neurons of mice deficient in Fig 4 or

Figure 7 Role of phosphoinositides in autophagy stages. PtdIns(3)P is important in autophagic trafficking. Autophagy is initiated by the recruitment of two protein complexes to a membrane source, the ULK1 complex (ULK1-Atg13-Fip200-Atg101) and the PI3K complex (Vps34-Beclin1-Atg14-Vps15). Dissociation of mTORC1 from the ULK1 complex is necessary for autophagy initiation which is PtdIns(3)P-dependent. Recruitment of the PI3K complex creates a positive feedback loop of PtdIns(3)P production and further ULK1 complex recruitment, and nucleation occurs with the interaction of the FYVE domain containing effector protein DFCP1 with PtdIns(3)P on omegasomes. This serves as a platform for the development of the isolation membrane, which is mediated by WIPI2, a WD40 domain containing PtdIns(3)P effector. The myotubularins MTMR3, MTMR6, MTMR8/MTMR9 complex and MTMR14 act to decrease PtdIns(3)P and inhibit autophagy initiation. The transmembrane protein Atg9 recruits vesicles for the formation of the isolation membrane, and the Atg16L-Atg12-Atg5-Atg3 complex lipidates LC3 to LC3-PE for incorporation into the isolation membrane. LC3 and p62 mediate interactions with the species targeted for autophagy. The Atg proteins are lost upon closure of the autophagosome, which matures by fusion with lysosomes. The myotubularins Ymr1, MTM1 and MTM-3 are required for normal autophagy maturation. ER, endoplasmic reticulum.

Vac14, enzymes which are required for normal PIKfyve function exhibit abnormal autophagy (Ferguson *et al.*, 2009).

The turnover of PtdIns(3)P and possibly PtdIns(3,5)P₂ may be accomplished by the action of phosphoinositide 3-phosphatases. There have been reports that decreased 3-phosphatase function results in increased induction of autophagy, as well as blocking of the maturation of autophagosomes. This may be a result of individual 3-phosphatases acting to degrade PtdIns(3)P at unique points in time and space. The myotubularins MTMR3 and MTMR8 in complex with MTMR9, MTMR6, and MTMR14 as well as the protein phosphatase PTP σ all negatively regulate autophagy induction (Martin *et al.*, 2011; Mochizuki *et al.*, 2013; Taguchi-Atarashi *et al.*, 2010; Zou *et al.*, 2012). Two myotubularins ymr1 and MTM-3, in yeast and *C. elegans*, respectively, have been shown to act at later stages and are required for turning over PtdIns(3)P in order for autophagosomes to mature normally (Cebollero *et al.*, 2012; Wu *et al.*, 2014). Additionally, the muscle defects arising from loss of MTM1 function are thought to result from aberrant autophagy, produced as a consequence of a late-stage block in autophagy, as well as an increase in mTORC1 signaling, which negatively regulates autophagy initiation (Al-Qusairi *et al.*, 2013; Fetalvero *et al.*, 2013).

Recently, a role for PtdIns(4)P and PtdIns(4,5)P₂ in normal lysosomal function has been shown, particularly for lysosomal regeneration in response to starvation in the process of autophagic lysosome reformation (Kistakis and Tooze, 2013; Rong *et al.*, 2012; Sridhar *et al.*, 2013). PtdIns(4)P, formed by Class III PI4K β is important in restricting the lysosomal cargo from being sorted out of the lysosome during starvation when recycling of lysosomal membrane is required (Sridhar *et al.*, 2013). PtdIns(4,5)P₂ is needed for normal tubule formation for lysosomal egress, and fission of these tubules away from the lysosome, via the action of PI5K1B and PI5K1A respectively (Rong *et al.*, 2012).

Concluding Remarks

Refinements in biochemical and microscopic techniques continue to provide new opportunities to dissect the role of phosphoinositides in determining organelle identity and function. Many details of the contribution of phosphoinositide kinases and phosphatases in regulating the localization and abundance of individual phosphoinositide species at the membrane-cytosol interface remain to be characterized. Increasingly it is being understood that the orchestrated turnover of one phosphoinositide species into another is required not only to initiate and terminate individual organelle processes, but the transition of phosphoinositides ensures orderly flow of traffic between networked organelle compartments. The number of effector proteins which interact with phosphoinositides on membrane organelles continues to grow, however, much remains to be discovered about their regulation and function. Coordination of phosphoinositides and their effector proteins in regulating membrane organelle trafficking is essential for normal cellular function, and when aberrant leads to many human diseases, including infection, cancer, and degenerative diseases.

Mechanisms of Eukaryotic Protein Secretion

The vast majority of soluble secretory proteins make use of the ER/Golgi-dependent pathway to get access to the extracellular space (Rothman and Wieland, 1996; Schekman and Orci, 1996; Figure 1). Entering this route of secretion requires the presence of N-terminal signal peptides that are recognized by SRP (Rapoport, 2007). Following a slow-down of translation, ribosomes carrying nascent chains with N-terminal signal peptides are directed to the cytoplasmic surface of the ER coupling protein synthesis to translocation into the ER lumen mediated by Sec61 (Osborne *et al.*, 2005). Translocation of newly synthesized chains proceeds in a largely unfolded form followed by folding of the translocation substrate into the native state within the ER lumen (Park and Rapoport, 2012). Once secretory proteins pass ER quality control (Hegde and Ploegh, 2010; Sitia and Braakman, 2003), they are delivered to the cell surface based on vesicular transport and, upon fusion of post-Golgi carriers with the plasma membrane, are released into the extracellular space (Rothman, 1994; Figure 1).

It was long believed that the presence of a signal peptide concomitant with a protein's ability to penetrate the lumen of the ER was an essential requirement for protein secretion from eukaryotic cells. This view was challenged by the identification of signal-peptide-lacking cytokines that mediate defined extracellular functions of fundamental physiological importance (Muesch *et al.*, 1990; Nickel, 2003) along with reports presenting direct evidence that they can be secreted in an ER/Golgi-independent manner (Engling *et al.*, 2002; Mignatti *et al.*, 1992; Rubartelli *et al.*, 1990; Trudel *et al.*, 2000). The most classical examples are fibroblast growth factor 2 (FGF2), a proangiogenic mitogen (Presta *et al.*, 2005), as well as interleukin-1 β (IL-1 β), a key pro-inflammatory cytokine (Garlanda *et al.*, 2013; Dinarello, 2009). For both molecules, the cell surface receptors on target cells have been identified and crystal structures of the corresponding ligand–receptor complexes are available (Pellegrini *et al.*, 2000; Plotnikov *et al.*, 2000; Schlessinger *et al.*, 2000; Vigers *et al.*, 1997). Based on this, alternative pathways of protein secretion that operate independently of the ER/Golgi system were proposed to exist in eukaryotic cells (Muesch *et al.*, 1990).

As illustrated in Figure 1, two principal types of unconventional secretion appear to exist that are exemplified by FGF2 and IL-1 β as cargo proteins. While FGF2 is not only excluded from the lumen of the ER, it does not enter any other type of vesicular intermediates inside cells. Instead, as detailed below, FGF2 is capable of translocating across plasma membranes to reach the extracellular space (Figure 1; Nickel, 2005; Schäfer *et al.*, 2004). This may also be the case for IL-1 β (Brough and Rothwell, 2007; Shirasaki *et al.*, 2014). However, a number of additional secretory routes for IL-1 β have also been described. IL-1 β has been described in membrane-bound intermediates of

the endocytic membrane system (Andrei *et al.*, 1999, 2004; Malhotra, 2013; Dupont *et al.*, 2011; Piccioli and Rubartelli, 2013). The identity of these intermediates has not unequivocally been clarified, however, a role for multi-vesicular bodies (MVBs) has been suggested (Qu *et al.*, 2009). In this case, IL-1 β localized in the cytoplasm would be internalized by endosomes resulting in its localization in intra-endosomal vesicles called exosomes. Alternatively, cytoplasmic IL-1 β might be initially captured by autophagosomes followed by delivery to endocytic compartments such as MVBs (Figure 1; Malhotra, 2013; Dupont *et al.*, 2011). This mechanism would be consistent with a proposed pathway of unconventional secretion in lower eukaryotes that has been described for acyl coenzyme A binding protein (AcbA/Acb1) (Malhotra, 2013; Bruns *et al.*, 2011; Duran *et al.*, 2010; Kinseth *et al.*, 2007). Other suggestions have been a role for secretory lysosomes (Rubartelli *et al.*, 1990; Andrei *et al.*, 1999; Piccioli and Rubartelli, 2013) or plasma membrane shedding, i.e., secretion of IL-1 β in microvesicles that form at the extracellular surface of cells and incorporate cytoplasmic material (Figure 1; Piccioli and Rubartelli, 2013; MacKenzie *et al.*, 2001). However, for these options of IL-1 β release, no unambiguous evidence has been presented and the exact mechanism remains elusive. Below, we comment on how these mechanisms of secretion may contribute to the cellular release of IL-1 β during an inflammatory episode.

Hallmarks of FGF2 Membrane Translocation during Unconventional Secretion

As illustrated in Figure 1, our current view on how FGF2 is secreted from cells is based on a mechanism characterized by direct translocation across plasma membranes, i.e., FGF2 is not incorporated into intracellular membrane-bound compartments as intermediates in this alternative pathway of secretion (Nickel, 2005; Schäfer *et al.*, 2004). Instead, FGF2 is capable of interacting with phosphoinositides at the inner leaflet of plasma membranes, a key step that initiates membrane translocation (Temmerman *et al.*, 2008; Temmerman and Nickel, 2009). This process, however, does not appear to rely on a protein-conducting channel but rather on the ability of membrane-recruited FGF2 to oligomerize concomitant with the formation of a membrane pore (Nickel, 2011; Steringer *et al.*, 2012). This structure has been proposed to have a toroidal architecture with the FGF2 oligomer in the center and the lipid binding sites being localized in the periphery. In a way, this structure might share structural similarities with toroidal membrane pores formed by components of the apoptotic machinery involved in the disintegration of the outer mitochondrial membrane (Terrones *et al.*, 2004; Qian *et al.*, 2008). Once FGF2 oligomers have formed membrane pores, membrane-proximal heparan sulphate chains of cell surface localized proteoglycans can act as

Figure 1 Principle pathways of protein secretion from eukaryotic cells.

an extracellular trap for FGF2 molecules resulting in their exposure on cell surfaces (Nickel, 2007; Zehe *et al.*, 2006). Thus, the biochemical and biophysical properties of FGF2 allow for a mechanism of membrane translocation with the cargo protein (= FGF2 monomer) forming its own translocation machinery (= membrane-inserted FGF2 oligomer) triggered by phosphoinositide-induced multimerization. This model is supported by evidence for membrane translocation of FGF2 in a fully folded state (Backhaus *et al.*, 2004; Torrado *et al.*, 2009) requiring the formation of defined oligomers during membrane pore formation. Further support for this model comes from the observation that Tec kinase, a non-receptor tyrosine kinase that has previously been described in the context of T cell development and activation (Yang *et al.*, 2000), is a regulatory factor of FGF2 secretion. The role of Tec kinase in FGF2 secretion was initially recognized through a genome-wide RNAi screen designed to identify factors involved in this process (Ebert *et al.*, 2010; Nickel, 2010). Tec kinase was further shown to phosphorylate FGF2, a process that facilitates the formation of membrane pores by FGF2 oligomers (Nickel, 2011; Steringer *et al.*, 2012). Since Tec kinase contains a PH domain that mediates both phosphoinositide-dependent membrane recruitment and enzymatic activation (Bradshaw, 2010), FGF2 phosphorylation is likely to occur at the inner leaflet of the plasma membrane (Nickel, 2011). Since FGF2 is a key signaling molecule in the context of many cancers, Tec kinase regulated secretion of FGF2 represents an interesting link to the up-regulation of PI3 kinases in many tumor cells (Liu *et al.*, 2009). PI3 kinases catalyze the formation of PI(3,4,5)P₃ and high cellular levels of this phosphoinositide are likely to support efficient secretion of FGF2 which, in turn, promotes tumor cell proliferation.

The Molecular Mechanism of FGF2 Membrane Translocation and Its Path of Discovery

Our current knowledge about the mechanism by which FGF2 physically traverses the plasma membrane to reach the extracellular space has previously been described explaining the sequence of events as they occur in a cell (Nickel, 2010, 2011; Nickel and Sedorf, 2008; Nickel and Rabouille, 2009; Rabouille *et al.*, 2012). Here, we would like to recount this path of discovery in chronological order.

In 2002, the setup of a cell-based assay to quantify FGF2 secretion was the starting point of these studies as this experimental system provided convincing evidence that FGF2 is secreted by a controlled mechanism (Engling *et al.*, 2002). It also confirmed observations by other laboratories demonstrating that FGF2 secretion does not result in the appearance of soluble FGF2 in cellular supernatants (Trudel *et al.*, 2000). Rather, following membrane translocation, FGF2 was found retained on cell surfaces bound to heparan sulphate proteoglycans. Further observations in the initial phase of these studies indicated that the mechanism of FGF2 secretion from cells is unusual in at least two ways. On the one hand we found that FGF2 has the ability to directly translocate across plasma membranes that had been affinity-purified as so-called inside-out vesicles (Schäfer *et al.*, 2004). This finding suggested that FGF2 is not only incapable of penetrating the lumen of the ER/Golgi system but also does not need to make use of

other membrane-bound intermediates such as endocytic compartments to reach the extracellular space. These results were initially interpreted as a possibility for a plasma membrane resident protein-conducting channel being responsible for membrane translocation of FGF2. This hypothesis appeared plausible also because ABC transporters were known in the plasma membrane mediating the externalization of peptides (McGrath and Varshavsky, 1989; Michaelis, 1993). However, a second key finding at the time was that FGF2 secretion from cells does not involve an unfolded form of FGF2 as an obligatory intermediate (Backhaus *et al.*, 2004). Since both peptide and protein-conducting channels from various membranes including the ER and mitochondria were known to form narrow channels through which largely unfolded translocation substrates are threaded, it appeared unlikely that a plasma membrane resident protein-conducting channel is behind the principle of FGF2 membrane translocation. This view was supported by additional findings demonstrating that membrane-proximal heparan sulphate proteoglycans on cell surfaces are required to complete FGF2 membrane translocation into the extracellular space (Zehe *et al.*, 2006). Since FGF2 binding to heparin depends on FGF2 being folded properly (Torrado *et al.*, 2009), folding of FGF2 is required for translocation to cell surfaces. The same is true for FGF2 binding to the phosphoinositide PI(4,5)P₂ that is both required for FGF2 recruitment at the inner leaflet and essential for FGF2 secretion from cells (Temmerman *et al.*, 2008; Temmerman and Nickel, 2009). Again, binding to PI(4,5)P₂ was found to require FGF2 in a folded form demonstrating that FGF2 needs to be folded to undergo membrane translocation (Torrado *et al.*, 2009). Finally, it was shown that FGF2 is capable of transporting other proteins out of cells based on engineered non-covalent interactions that depend on proper folding (Torrado *et al.*, 2009). These experiments confirmed earlier findings mentioned above and unequivocally demonstrated that unfolded forms are not obligatory intermediates in FGF2 membrane translocation and secretion from cells. In conclusion, as illustrated in Figure 1, it was clear that unconventional secretion of FGF2 occurs by direct translocation across plasma membranes, involves sequential interactions with the phosphoinositide PI(4,5)P₂ at the inner as well as heparan sulphates at the outer leaflet, and is based on a mechanism that is likely not only to be compatible but rather requires FGF2 in a properly folded form. The latter aspect was interpreted as a potential quality control mechanism ensuring that only folded and, therefore, biologically active forms of FGF2 reach the extracellular space (Torrado *et al.*, 2009). Thus, in 2009, the search for a novel type of protein translocation across membranes that is independent of protein-conducting channels began.

PI(4,5)P₂-Induced FGF2 Oligomerization and Membrane Pore Formation: A Transient Intermediate in FGF2 Membrane Translocation

As a starting point to obtain insight into the mechanism of FGF2 membrane translocation, we sought to conduct a global analysis of gene products involved in unconventional secretion of FGF2. In 2010, a genome-wide RNAi screen was completed identifying a large set of candidate proteins

potentially involved in FGF2 membrane translocation. The bioinformatical analysis, validation and functional analysis of these proteins is still ongoing, however, we were lucky to identify and validate one gene product already during pilot experiments that turned out to play a key role, Tec kinase (Ebert *et al.*, 2010). Both RNAi-mediated downregulation and pharmacological inhibition of Tec kinase impaired FGF2 secretion. Moreover, biochemical experiments revealed a direct interaction and phosphorylation of FGF2 by Tec kinase at tyrosine residue 81 (Ebert *et al.*, 2010). FGF2 variant forms lacking this tyrosine were found to be impaired in secretion and, most importantly, a phosphomimetic substitution of tyrosine 81 rendered FGF2 secretion from cells independent of Tec kinase providing conclusive evidence for its role in FGF2 secretion. The identification of Tec kinase was particularly intriguing as this protein contains a PH domain that mediates phosphoinositide-dependent recruitment to the inner leaflet of plasma membranes (Bradshaw, 2010). Tec kinase has a binding preference for PI(3,4,5)P₃ and this interaction causes activation of its enzymatic activity (Bradshaw, 2010). With this finding, principal components required for FGF2 membrane translocation were discovered: the phosphoinositides PI(4,5)P₂ and PI(3,4,5)P₃, the heparan sulphate chains of cell surface proteoglycans and Tec kinase. All of these factors are physically associated with the plasma membrane, the proposed site of FGF2 membrane translocation.

But what is the function of Tec kinase mediated tyrosine phosphorylation in FGF2 membrane translocation? To tackle this problem, we decided to generate a recombinant form of FGF2 in which tyrosine 81 was substituted by an unnatural amino acid, p-carboxymethylphenylalanine (pCMF). This residue is a close structural mimetic of a phosphotyrosine, so we analyzed the biochemical and biophysical properties of this variant form of FGF2 in biochemical reconstitution experiments. Though occurring independently of the phosphomimetic residue, a key observation in these experiments was that binding to PI(4,5)P₂-containing membranes causes FGF2 to oligomerize (Steringer *et al.*, 2012). Based on small fluorescent tracers and various kinds of artificial membranes including large and giant unilamellar vesicles, it became clear that FGF2 oligomers form membrane pores allowing for the passage of small molecules. In addition, transbilayer diffusion of membrane lipids was observed during FGF2-induced membrane pore formation suggesting a toroidal architecture (Steringer *et al.*, 2012). Most intriguingly, a phosphomimetic substitution in FGF2 (FGF2-Y81pCMF) strongly increased the rate of membrane pore formation providing direct evidence that Tec kinase mediated phosphorylation of FGF2 facilitates membrane insertion of FGF2 oligomers. This, in turn, suggests that inhibition of FGF2 secretion in the absence of Tec kinase activity (e.g., following RNAi-mediated down-regulation) is due to inefficient membrane insertion of FGF2 oligomers as membrane translocation intermediates.

But how are membrane-inserted FGF2 oligomers removed from the plasma membrane in order to appear on cell surfaces? The proposed mechanism of PI(4,5)P₂-induced membrane pore formation actually provides a simple explanation for our early findings establishing a role for cell surface heparan sulphates in the final step of FGF2 membrane translocation (Nickel, 2007; Zehe *et al.*, 2006). Since basic residues

in FGF2 that are required for heparin binding are also needed for binding to PI(4,5)P₂ (e.g., lysine 133; Temmerman *et al.*, 2008) it is possible that binding of FGF2 to heparan sulphates versus PI(4,5)P₂ is mutually exclusive. At the same time, the affinity of FGF2 for heparan sulphates is about 100 times higher ($K_D \approx 10$ nM; Faham *et al.*, 1996) compared to PI(4,5)P₂ ($K_D \approx 1$ μ M; Temmerman and Nickel, 2009). This suggests that, once FGF2 molecules become accessible to extracellular heparan sulphates as part of oligomers within a lipidic membrane pore, they can compete against PI(4,5)P₂ for binding to FGF2. We propose that this is the underlying mechanism by which cell surface heparan sulphates mediate the final step of FGF2 membrane translocation resulting in the exposure of FGF2 on cell surfaces. This model also provides a basis for directionality of FGF2 membrane translocation that is defined through sequential interactions of FGF2 with PI(4,5)P₂ at the inner leaflet and heparan sulphates at the outer leaflet. It also emphasizes that PI(4,5)P₂ is not only required for membrane recruitment of FGF2 but also to support oligomerization in the context of plasma membranes. Finally, due to its cone-shaped structure, PI(4,5)P₂ is likely to be important for the toroidal architecture of lipidic membrane pores induced by FGF2 oligomerization. Direct experimental evidence for this view comes from the fact that diacylglycerol, a membrane lipid with the opposite cone-shaped structure of PI(4,5)P₂ inhibits transbilayer diffusion of membrane lipids during membrane pore formation (Steringer *et al.*, 2012). Thus, PI(4,5)P₂ is likely to be required to stabilize the high membrane curvature that is generated during the formation of a toroidal membrane pore (Figure 2).

Understanding the Regulation of IL-1 β Processing

For almost 30 years, since the discoveries that the 'master' cytokine IL-1 β lacks a signal peptide (Auron *et al.*, 1984) and does not traffic through the ER and Golgi (Rubartelli *et al.*, 1990), immunologists have speculated how IL-1 β is secreted. Given the importance of IL-1 β to the host defense response, and its seemingly unique biology, understanding the mechanism of IL-1 β secretion is of outstanding fundamental interest, and holds considerable downstream therapeutic potential. As discussed above, despite a number of interesting ideas, all supported by biochemical data, no consensus for a mechanism of IL-1 β secretion exists (Lopez-Castejon and Brough, 2011).

IL-1 β is produced by many cells, most commonly those of macrophage lineage, as a pro-IL-1 β precursor. This precursor is expressed in response to pathogen associated molecular patterns (PAMPs) or damage associated molecular patterns (DAMPs) that bind to pattern recognition receptors (PRRs) on macrophages to upregulate pro-inflammatory gene expression (Schroder and Tschopp, 2010; Takeuchi and Akira, 2010). PAMPs are motifs carried by pathogens, such as bacterial endotoxin (or LPS) of Gram-negative bacteria, and DAMPs are commonly endogenous molecules released by necrosis. In macrophages this initial stimulus is commonly referred to as a 'priming' step and pro-IL-1 β is inactive and remains intracellular until a further PAMP or DAMP stimulation activates cytosolic PRRs, often of the NLR family, to form large multi-protein complexes called inflammasomes (Latz *et al.*, 2013).

needed for, i.e., why do cells need an alternative to the ER/Golgi-dependent secretory pathway? One way of looking into this was to analyze FGF2 variant forms that contain engineered signal peptides at their N-termini. Following expression in mammalian cells we asked whether they are secreted in an ER/Golgi-dependent manner and whether the secreted population is biologically active (Wegehingel *et al.*, 2008). The first question by no means was a trivial one since FGF2 is a lectin that, upon binding to heparan sulphate chains, tends to oligomerize. So premature binding to its ligands in the lumen of the *trans*-Golgi network might cause aggregation resulting in a block of secretion and potentially even disintegration of Golgi structure. However, FGF2 containing a signal peptide derived from FGF4 was secreted with high efficiency (Wegehingel *et al.*, 2008), yet a remarkable difference to authentic FGF2 was observed. FGF2 secreted by the ER/Golgi-dependent pathway was no longer retained on cell surfaces but rather accumulated in the supernatant of cells. When analyzed by biochemical means we realized that the signal-peptide-containing version of FGF2 was modified running as a rather undefined population with an apparent molecular weight of about 80 kDa. A biochemical analysis revealed that, when forced to travel through the lumen of the ER/Golgi system, FGF2 becomes posttranslational modified by O-linked chondroitin sulphates. As a consequence, this form of FGF2 failed to interact with heparan sulphates on cell surfaces resulting in its accumulation in cellular supernatants (Wegehingel *et al.*, 2008). Since binding of FGF2 to heparan sulphate proteoglycans is essential to form ternary signaling complexes containing FGF high affinity receptors, FGF2 secreted through the ER/Golgi-dependent pathway is impaired in its biological activity. Based on these findings, it is a plausible hypothesis that unconventional secretion permits export from cells of unmodified forms of FGF2 that retains their biological activity. Only limited evidence for such studies exists for IL-1 β . IL-1 β directed through the ER/Golgi is efficiently secreted, but is also N-glycosylated (Baldari *et al.*, 1987; Pecceu *et al.*, 1991). However, how glycosylation affects the biological function of IL-1 β is not clear with evidence suggesting that glycosylated IL-1 β is active (Baldari *et al.*, 1987), and evidence suggesting that glycosylation results in a 95% inhibition of biological activity (Fleer *et al.*, 1991). This concept may actually reflect a general aspect of unconventional secretory processes, the ability of mammalian cells to secrete proteins avoiding modifications that potentially occur in the lumen of the ER/Golgi system such as glycosylation.

Another interesting aspect emerges when one considers the evolution of the FGF protein family (Itoh and Ornitz, 2008). Four of the more than 20 members have been defined as so-called intracellular FGFs (FGF 11–14, termed iFGFs) that are not secreted from cells but are functioning solely inside cells. The iFGFs are believed to be the ancestors of the FGF family (Itoh and Ornitz, 2008). It appears possible that they were followed by FGF1 and FGF2, the two members that are secreted by unconventional means. Only later in evolution, signal-peptide-containing FGFs appeared complementing the FGF family as we know it today. This suggests that FGF1 and FGF2 were the first family members that managed to exit cells in order to execute new functions outside cells. But how did FGF2 find its way into the extracellular space? Based on the

mechanism proposed here (Figure 2), one may wonder whether the ability of FGF2 to form lipidic membrane pores is related to membrane pores generated by some bacterial toxins (Shai, 1999) or by components of the apoptotic machinery that promote the formation of toroidal membrane pores in the outer membrane of mitochondria to cause programmed cell death (Qian *et al.*, 2008; Garcia-Saez *et al.*, 2006). In case of FGF2, however, these pores are not formed to destruct the membrane but rather to build transient intermediates of membrane translocation. Unconventional secretion may allow for a double life of proteins with functions in different localizations based on an equilibrium that can be dynamically changed by cells to match physiological needs. This is also exemplified by the IL-1 family member IL-1 α . Also secreted by poorly defined nonconventional pathways, IL-1 α is also actively trafficked to the cell nucleus (Luheshi *et al.*, 2009b), where it is proposed to have functions leading to the 'dual function' hypothesis (Luheshi *et al.*, 2009a). By contrast, signal-peptide-containing proteins can be considered professional secretory proteins that are doomed for quantitative secretion with their sole function in the extracellular space.

Future Perspectives

To challenge the model of FGF2 membrane translocation discussed in this article new experimental strategies are required to verify its hallmarks and predictions. A major aim will be to reconstitute a full cycle of FGF2 membrane translocation with chemically defined components. A promising approach will be to use giant unilamellar vesicles with heparin trapped in their lumen to mimic membrane-proximal cell surface heparan sulphates. This will allow for testing the capability of fluorescently labeled species of phosphomimetic FGF2 to physically traverse the membrane under these conditions, a key prediction of the model shown in Figure 2. In this context, it is also attractive to address other unconventional secretory proteins such as HIV-Tat, a critical transactivator of transcription required for the life cycle of HIV (Jeang *et al.*, 1999). In addition to its classical role in the nucleus of infected T cells, HIV-Tat was shown to be secreted (Ensoli *et al.*, 1990, 1993) and is present in substantial amounts in the blood of HIV-infected individuals (Xiao *et al.*, 2000). In cell-based experiments, it has been shown that HIV-Tat is indeed secreted from infected T cells using an ER/Golgi-independent pathway (Rayne *et al.*, 2010a). These studies further suggested that HIV-Tat is capable of translocation across plasma membranes, a process that depends on the ability of HIV-Tat to bind to the phosphoinositide PI(4,5)P₂ (Rayne *et al.*, 2010a,b). Another example is FGF1, the second FGF family member secreted by unconventional means (Nickel, 2003). Its secretion has been suggested to occur at the level of plasma membranes depending on binding to acidic phospholipids and local destabilization of membrane integrity (Prudovsky *et al.*, 2008). As discussed above, it is not even clear whether the basic principle behind unconventional secretion of IL-1 β differs from that of FGF2. This is because the reported evidence for a role of endocytic sub-compartments is of indirect nature. A critical shortcoming of experiments supporting a role of, for example, MVBs and exosomes is that IL-1 β so far has not been

localized to transport vesicles whose nature as intermediates of this pathway has been demonstrated unambiguously (Zhang and Schekman, 2013). Therefore, one may wonder whether the substantial structural similarity of mature IL-1 β to FGF2 as well as the typical disruption of plasma membrane integrity observed during LPS/ATP triggered secretion of IL1 β (Shirasaki *et al.*, 2014) indicates a core mechanism that resembles the one we propose for FGF2 (Figure 2).

Other key aims in the analysis of the molecular mechanism, by which FGF2 is secreted from cells to analyze the structure–function relationship of the membrane-inserted FGF2 oligomers as translocation intermediates in unconventional secretion and the identification of further components of this pathway. In the long run, we aim to develop pharmacological inhibitors against each molecular component and step of this process. Furthermore, this knowledge will allow for systematically addressing the question whether indeed multiple, unrelated pathways of unconventional secretion exist or whether one common principle is behind this phenomenon with variations at the regulatory level depending on cell type and physiological conditions.

Glossary

Conditional deletion The genetic ablation of a specific gene in a cell-specific or temporal-restricted fashion in a multicellular organism by use of the site-specific recombinase technology. Frequently, this is achieved by flanking the target region for deletion by LoxP sequences and placing the Cre recombinase under the control of a cell type-specific or regulatable promoter that can be switched on only in the cells of interest. An example is the use of the rat insulin promoter to restrict the expression of Cre in β -cells and therefore achieve the specific ablation of the gene of interest only in β -cells. In some cases the Cre recombinase may be fused to a protein that may be activated by a ligand. An example would be a Cre recombinase-estrogen receptor fusion protein that upon treatment with the estrogen antagonist, tamoxifen, the fusion protein translocates to the nucleus to mediate deletion of the LoxP-flanked gene. The gene deletion can generate a heterozygous or a homozygous state.

Knock out The deletion of a gene in all the cells of an organism. It can be obtained in a heterozygous or homozygous state.

Polyubiquitination A posttranslational protein modification consisting of the formation of a chain of

molecules of ubiquitin, a 76 amino acid protein, linked one to another, and originated from the linkage of the first ubiquitin to a single lysine residue in the target protein. The presence of ubiquitin chain signals the disposal of the protein via the 26S proteasome or may signal trafficking, such as internalization from the cell membrane.

RNA interference (RNA_i) technology In the presence of a small interfering (si) RNAs for a gene, the activity of that gene is reduced, often giving a phenocopy of a hypomorphic allele in the gene. The technology is based on the annealing of a short antisense RNA to the corresponding mRNA and consequent destruction of the specific mRNA molecule or translational inhibition.

Signaling pathway A chain of molecular events that converts the presence of a stimulus into a physiological response. After the activation of the response, regulatory mechanisms reduce the sensitivity of the cell to the signal.

Synthetic lethality A lethal effect caused by the combination of the inactivation of two genes, or specific inhibition of their products. A functional interaction among the gene products or a reciprocal compensation often underlies a synthetic lethal interaction.

Introduction

The endoplasmic reticulum (ER) is a membranous system that expands from the outer membrane of the nuclear envelope and plays several fundamental functions. The ER coordinates the biosynthesis and input of proteins into the secretory pathway along which they are transported to their final destination (the Golgi apparatus, lysosomes, the endocytic compartment, plasma membrane, or the extracellular milieu). The importance of protein secretion in humans is underlined by the estimation that about one-third of proteins encoded by the human genome enter the secretory pathway and also many secreted proteins, such as hormones, growth factors, digestive enzymes, and blood proteins, are fundamental for human physiology. Cells specialized in secretion of large amounts of proteins, such as plasma cells, pancreatic endocrine or exocrine cells, and hepatocytes, exhibit a marked expansion of the ER indicating that this organelle has the striking ability to adapt its size to the needs of the cell. The ER is also the site of biosynthesis of lipid and sterols, essential membrane components that are required for compartmentalization of eukaryotic cells. The biophysical properties of membranes differ between different organelles to ensure proper localization and compartmentalization of proteins within the cell, to optimize

activities of membrane-localized enzymes and to direct protein trafficking mediated by vesicle transport. The ER is the principal site for calcium (Ca^{++}) storage and signaling and detoxification reactions. The ER orchestrates all these activities and consequently is susceptible to stress if the balance is perturbed.

One crucial requirement for cell survival is the ability to rapidly respond to environmental changes and adapt to it. Alterations in the extracellular environment, such as decreased oxygen or nutrient supply, as well as nutrient excess such as cholesterol or fatty acids, or changes in intracellular homeostasis, such as Ca^{++} flux, altered redox status, cell cycle progression, cellular responses to hormonal, or growth factor stimulation, can change the protein-folding load and/or efficiency in the ER leading to accumulation of misfolded proteins. Overall, this article focuses on the current knowledge on how the ER perceives alterations in cell homeostasis and communicates information to other organelles to elicit an appropriate biological response. This communication is mediated in part through a collection of signaling pathways termed the unfolded protein response (UPR) (Schroder and Kaufman, 2005b; Walter and Ron, 2011). The UPR is essential for cells to adapt to altered cellular environments, and if insufficient, initiates a cell death response (Tabas and Ron, 2011; Cao and Kaufman, 2014).

Protein Synthesis, Folding, and Quality Are Tightly Controlled in the ER

Proteins enter the ER during their synthesis. In this co-translational process, the polypeptide is translocated across the ER membrane through the Sec61 channel in an unfolded state. As nascent polypeptides enter the ER lumen during synthesis, they fold and assemble into their native conformations by the assistance of resident chaperones, which include the peptide-binding chaperones, such as binding immunoglobulin protein (BiP)/glucose-regulated protein of 78 kDa (GRP78) and GRP94, and their associated co-chaperones, including the DnaJ family members. As the ER is an oxidizing environment, folding involves the formation of disulfide bonds. In addition to peptide-binding chaperones, enzymes that catalyze protein folding include thiol-disulfide isomerases which catalyze disulfide bond formation (the protein disulfide isomerase (PDI) protein family, ERp57, ERp72) by oxidation of protein thiols (2 SH to S-S) at the expense of reduction of their own disulfide bonds (S-S to 2 SH), and peptidyl-prolyl cis-trans isomerase family members, such as cyclophilin B, that enhance the rate-limiting steps of protein folding. As the protein enters the ER it is subject to addition of core oligosaccharide structures to selective asparagine (N) residues that have the consensus Asn-X[P]-Ser/Thr where X may be any residue except proline. N-linked glycosylation increases protein solubility and trimming of the oligosaccharide core is coupled with interactions with lectins that assist protein folding, trafficking, and even degradation within the early secretory pathway (Ferris *et al.*, 2014). Properly folded proteins transit to the Golgi apparatus and are further modified and sorted to their final destination or stored in vesicles (granules) until a signal stimulates their release into the extracellular space.

The ER harbors an exquisite surveillance system that ensures only properly folded and assembled proteins traffic to the Golgi apparatus, a process termed ER protein quality control (ERQC). Proteins that do not pass ERQC are diverted to degradation by retro-translocation back into the cytosol, polyubiquitination, and degradation by the 26S proteasome in a process termed ER-associated protein degradation (ERAD) (Hampton and Sommer, 2012) or by a process of bulk auto-digestion called autophagy (Buchberger, 2014).

Misfolding of mutant proteins in the ER is the cause of many human genetic diseases. These pathological conditions and those associated with cytosolic misfolded proteins, collectively referred to as 'conformational diseases,' are outside the scope of this article.

ER protein-folding homeostasis depends on a strict coordination between the rates of protein synthesis, folding, and degradation. Perturbations, such as an increase in the rate of protein synthesis, reduced folding capacity, inefficient disulfide bond formation, energy depletion, changes in the ER redox status, or inhibition of degradation cause accumulation of misfolded protein in the ER, a condition termed ER stress.

The Discovery of the UPR as an Example of Interorganellar Communication

The UPR was discovered in the mid-1980s when it was found that misfolded proteins bind to the protein chaperone BiP/GRP78, a process that activates transcription of a set of genes,

originally characterized as genes induced upon glucose deprivation of cells, hence the name glucose-regulated proteins (Dorner *et al.*, 1987, 1989; Kozutsumi *et al.*, 1988). Subsequently, the first and most conserved sensor of misfolded proteins was discovered in yeast in the early 1990s through a genetic selection. Since the gene was previously identified as one required for growth of yeast in the absence of inositol, it was termed inositol requiring enzyme (IRE). Subsequently, mammalian homologs were identified, IRE1 α and IRE1 β . It was later discovered that IRE1 has dual catalytic activities of protein kinase and endoribonuclease (RNase) that cleaves an intron from its substrate Hac1p mRNA in yeast and X-box binding protein 1 (XBP1) mRNA in metazoans. Subsequently, PKR-related ER kinase (PERK) was identified as a protein kinase that phosphorylates the α -subunit of eIF2 to attenuate protein synthesis (Harding *et al.*, 1999) and activating transcription factor 6 (ATF6) was identified as a transcription factor that is cleaved from the ER membrane upon ER stress to generate a cytosolic fragment that migrates to the nucleus to activate gene transcription (Schroder and Kaufman, 2005b).

The UPR can be experimentally activated by inhibition of N-glycosylation (by the antibiotic tunicamycin), nutrient deprivation (amino acids or glucose), Ca⁺⁺ depletion (thapsigargin, an inhibitor of the sarcoplasmic reticulum Ca⁺⁺-dependent ATPase, SERCA), reductive stress (dithiothreitol or homocysteine), increases in protein expression (increased protein-folding load), synthesis of mutant proteins that misfold or inhibition of ERAD (inhibitors of the 26S proteasome). In mammalian cells the activation of the UPR provokes three biological responses to relieve cells from ER stress: (1) attenuation of protein synthesis to decrease protein influx into the ER, (2) stimulation of protein chaperone synthesis to promote protein folding, and (3) increased expression of factors required for ERAD or autophagy, i.e., to increase removal of terminally misfolded proteins (Schroder and Kaufman, 2005b). However, if these mechanisms fail and ER stress and protein misfolding persist, the UPR initiates an apoptotic pathway to cell death, which can contribute to the pathogenesis of many diseases (Wang and Kaufman, 2012).

ER Transmembrane Proteins Sense Misfolded Proteins to Activate UPR Signaling

In mammalian cells, ER stress activates the three sensors: IRE1 α/β , PERK, and ATF6 α . As depicted in the inset of Figure 1, IRE1 and PERK are type I transmembrane proteins that share a related luminal N-terminal ER sensing domain whereas ATF6 α is a type II transmembrane protein that has a C-terminal sensing domain. Each protein has a cytosolic portion that transduces the signal. Both IRE1 and PERK contain a cytosolic serine/threonine protein kinase domain but IRE1 has an additional RNase domain. The cytosolic N-terminal domain of ATF6 α is a basic leucine zipper (bZIP) transcriptional activator. Under normal conditions, the luminal domains of the three sensors bind BiP and are maintained in an inactive state. When misfolded proteins accumulate in the ER, BiP binding is diverted to the misfolded proteins, and this permits dimerization and activation of the protein kinases IRE1 and PERK and release of ATF6 α from the ER for

Figure 1 The intracellular signaling pathways induced during the UPR in metazoans. In the inset: a schematic representation of the domain organization of the three ER transmembrane protein sensors of the UPR: IRE1 α , PERK, and ATF6 α . The accumulation of unfolded/misfolded proteins in the ER lumen sequesters BiP and induces the dimerization and consequent *trans*-autophosphorylation of IRE1 α and PERK protein kinase. Phosphorylation of IRE1 α activates its endoribonuclease activity to initiate splicing of XBP1 mRNA. Upon release from BiP, ATF6 α transits to the Golgi compartment for processing by S1P and S2P cleavage to release the transcriptional active proteolytic fragment of 50 kDa, ATF6 α (N). The different arms of the UPR induce in concert a wide number of transcriptional and translational responses and regulation of selective RNAs degradation as explained in detail in the text.

trafficking to the Golgi compartment (Figure 1). The recent X-ray crystal structures of yeast and mammalian IRE1 and PERK provided insights in the molecular mechanism of ER stress sensing (Kimata and Kohno, 2011).

IRE1 Is an Evolutionarily Conserved UPR Sensor

IRE1 is the only UPR sensor conserved in all eukaryotes, from yeast to mammals, indicating that it plays fundamental functions for the cell. Mammalian IRE1 exists in two isoforms encoded by two homologous genes: IRE1 α is the best characterized and ubiquitously expressed while IRE1 β expression is restricted to the intestinal and lung epithelial cells where it may play a role in lipid adsorption. ER stress induces IRE1 α oligomerization and *trans*-autophosphorylation of juxtaposed kinase domains to activate the RNase domain (Figure 1). The RNase activity initiates unconventional splicing of the XBP1 mRNA that removes an internal 26-nucleotide intron to create

a translational frameshift. Translation of the spliced transcript produces XBP1s (s stands for spliced), a potent bZIP transcription factor that enters the nucleus and activates the transcription of UPR genes, notably chaperones or components of ERAD that have a UPR element (UPRE) in their promoter regions (Figure 1). IRE1 can also cleave mRNAs leading to their degradation, a process named regulated IRE1 α -dependent RNA decay or mediate the degradation of selected microRNAs (miRNAs) (Chitnis *et al.*, 2013; Coelho and Domingos, 2014). Activation of IRE1 α also induces a conformational change that allows the sensor to bind to the adaptor protein tumor-necrosis factor α receptor-associated factor 2 (TRAF2) and 6 (TRAF6) to contribute to an inflammatory response signaling through activation of apoptosis signal regulating-kinase 1 (ASK1) and the c-Jun N-terminal kinase (JNK) and activation of nuclear factor kappa B (NF- κ B) (Urano *et al.*, 2000; Wang and Kaufman, 2012). Overall, these discoveries highlight the multiplicity of molecular mechanisms that mediate the IRE1 α arm of the UPR.

PERK-Mediated Phosphorylation of α -Subunit of the Eukaryotic Translation Initiation Factor 2 Regulates mRNA Translation and Induces Death Signals

Upon ER stress, PERK undergoes dimerization/oligomerization and *trans*-autophosphorylation that activates the phosphorylation on Serine-51 of the α -subunit of eIF2 (eukaryotic translation initiation factor 2). This modification blocks eIF2 recycling and causes a shortage of the ternary complex (eIF2-GTP-Met-tRNAi) required for translation initiation. As shown in **Figure 1**, upon phosphorylation of the α -subunit of eIF2 (eIF2 α), protein synthesis is globally attenuated to reduce the protein flux into the ER. Paradoxically, activating transcription factor-4 (ATF4) mRNA, as well as a rapidly growing list of additional mRNAs, is preferentially translated under these conditions due to the presence of open reading frames within the 5'-untranslated region of its mRNA (Harding *et al.*, 2000a). ATF4 induces the expression of genes involved in ER-function antioxidant responses and amino acid biosynthesis and transport, as well as ER-stress-induced apoptosis (**Figure 1**; Harding *et al.*, 2003; Han *et al.*, 2013a). PERK was also reported to phosphorylate nuclear factor erythroid 2 (NF-E2) p45-related factor 2 (NRF2) to induce antioxidant response genes, including heme oxygenase1 and glutathione S-transferase. However, the gene expression changes induced by PERK activation are completely prevented by mutation at the Ser51 phosphorylation site to Ala in fibroblasts, suggesting all transcriptional regulation downstream of PERK activation is mediated through eIF2 α phosphorylation (Lu *et al.*, 2004).

ATF6 Is a Membrane-Bound Transcription Factor Regulated by Proteolysis

ATF6 α is the third arm of the mammalian UPR. The ATF6 β isoform is a distantly related homolog of ATF6 α and both are expressed in all tissues, although in mammals ATF6 β does not activate UPR gene expression. ATF6 α is an ER-resident transcription factor. As shown in **Figure 1**, during ER stress, ATF6 α is released from BiP and traffics to the Golgi apparatus, where it is sequentially cleaved by site-1 protease (S1P) and site-2 protease (S2P) at the transmembrane sites to release a cytosolic portion, p50 ATF6 α (N), that migrates to the nucleus to activate transcription (Shen and Prywes, 2005). In the nucleus ATF6 α (N) acts independently or synergistically with XBP1s to induce UPR target genes having the ER stress element (ERSE) in their promoter regions (Wu *et al.*, 2007; Yamamoto *et al.*, 2007). Interestingly, S1P and S2P are also responsible for cleavage of SREBPs (sterol-regulatory element binding proteins) that regulate lipid and cholesterol biosynthesis at the ER through activating transcription of lipid biosynthetic genes in response to reduced lipid or cholesterol levels.

The UPR Pathways Have Distinct and Overlapping Roles

Studies in genetically manipulated cells and organisms indicated that the three arms of the UPR provide different functions depending on the cell type and differentiation state. The IRE1 α /XBP1 pathway is particularly important for differentiation of cells that secrete large amounts of protein, such as plasma cells, pancreatic acinar, and β -cells (Wang and

Kaufman, 2012; Moore and Hollien, 2012). In an exocrine model of *in vitro* differentiation, inhibition of IRE1 α RNase activity did not alter the cellular response to ER stress but reduced membrane expansion (Cross *et al.*, 2012). These results suggest that in this model system, IRE1 α may play a more significant role in ER expansion associated with differentiation of secretory cell type than adaptation to ER stress (Kaufman *et al.*, 2002).

Studies in *Caenorhabditis elegans*, a nematode model of development, have provided a unique approach to study the UPR through application of RNA interference (RNAi) technology to inactivate genes, the use of mRNA microarray expression technology and the advantage of that each UPR sensor is encoded by a single gene. In *C. elegans*, the *Ire-1/Xbp1* pathway mediates the majority of UPR signaling during normal development and in response to acute ER stress. Deletion of either *atf6* or *pek-1* or their combination did not create a significant phenotype. In contrast, deletion of either *atf6* or *pek-1* was essential for the larval development in either *ire1* (RNAi) or *xbp-1* (RNAi) animals indicating that the two arms complement each other. Also upon acute ER stress, at least two coordinated transcriptional responses mediated by either *atf-6* or *pek-1* are required together with *ire-1/xbp1*. These findings indicate that *Ire-1/Xbp1* pathway is the most significant UPR pathway in *C. elegans* (Shen *et al.*, 2005).

Recent studies using *C. elegans* deleted in *ire-1* unveiled a link between ER homeostasis and nonsense-mediated RNA decay that degrades mRNAs carrying premature stop codons created by nonsense mutations (Sakaki *et al.*, 2012). Nonsense-mediated RNA decay prevents expression of C-terminal truncated proteins that would misfold. It was proposed this new connection protects cells from toxic effects of truncated proteins that are translocated into the ER and misfold and is an example of how the UPR intersects with other intracellular signaling pathways.

Chronic UPR Activation Causes Apoptosis in Mammalian Cells

Cells exposed to intense and/or chronic ER stress undergo apoptosis (Tabas and Ron, 2011; Logue *et al.*, 2013). Swelling and dilation of the ER is a hallmark of chronic ER stress. The PERK-eIF2 α -ATF4 arm of the UPR is a primary determinant for apoptosis since it culminates in the induction of the pro-apoptotic transcription factor C/EBP homologous protein (CHOP)/growth-arrest and DNA damage inducible protein (GADD153) (Rutkowski *et al.*, 2006). CHOP up-regulates apoptosis-related genes including the death receptor DR5 and the pro-apoptotic proteins BIM and PUMA, the pseudokinase TRB3 to promote cell death in response to ER stress (Lu *et al.*, 2014; Wang and Kaufman, 2012). CHOP also mediates the induction of GADD34, a regulatory subunit of protein phosphatase 1 (PP1) that dephosphorylates eIF2 α (**Figure 1**). This feed-back loop on eIF2 restores mRNA translation after the protein-folding defect is resolved. However, if protein misfolding is not resolved, resumption of protein synthesis causes oxidative stress leading to apoptosis (Han *et al.*, 2013a). This is suggested by the protection from ER-stress-induced tissue damage exhibited by CHOP or GADD34 knockout mice and

rescue from protein misfolding stress in cells treated with inhibitors of PP1 or GADD34, as well as antioxidants (Wang and Kaufman, 2012). Thus, when protein folding is disturbed, the sustained action of GADD34 increases protein synthesis leading to cell death. Moreover, CHOP induces oxidoreductin 1 (ERO1 α), an ER localized oxidoreductase that hyperoxidizes the ER environment and further commits cells to apoptosis (Li *et al.*, 2009). In addition, CHOP suppresses expression of anti-apoptotic B-cell lymphoma-2 (Bcl-2) protein (McCullough *et al.*, 2001) causing an increased production of reactive oxygen species and injury to the cell (Kim *et al.*, 2008). The sensitivity of the ER to oxidative stress revealed a link between ER and mitochondria, that are also physically associated at specific sites called mitochondrial-associated membranes that are likely sites of ER-stress-induced Ca⁺⁺ release from ER stores for uptake into mitochondria (Kaufman and Malhotra, 2014). The consequence of dumping ER Ca⁺⁺ into mitochondria initially activates oxidative phosphorylation to produce ATP, but prolonged or excessive Ca⁺⁺ loading leads to permeability transition of the inner mitochondrial membrane and activation of the intrinsic caspase cascade to cause apoptosis in a number of disease states (Cao and Kaufman, 2014).

IRE1 α is also implicated in cell death. Activated IRE1 α recruits the adaptor TRAF2 that signals through the stress-activated protein kinases ASK1 and JNK (Urano *et al.*, 2000; Nishitoh *et al.*, 2002).

Another link between IRE1 α and apoptosis is provided by the demonstration that hyperactivated IRE1 α causes relatively nonspecific RNA degradation that can lead to cell death (Ghosh *et al.*, 2014). In addition, thioredoxin-interacting protein (TXNIP) expression is induced by IRE1 α -mediated degradation of miR-17 that stabilizes TXNIP mRNA. Elevated levels of TXNIP activate the NLRP2 inflammasome and cause procaspase-1 cleavage and IL- β secretion. Accordingly, *Txnip* deletion reduced β -cell death during ER stress (Lemer *et al.*, 2012).

The Role of the UPR in Human Health and Disease

One of the remarkable findings regarding the UPR is that extracellular stimuli or fluctuations in intracellular homeostasis can disrupt the protein-folding environment of the ER (Figure 2). Therefore, through its unique ability to monitor the protein-folding status, UPR signaling senses perturbations

Figure 2 ER stress in disease. Pathophysiological conditions such as high/low glucose, hypoxia, high levels of fatty acids or cholesterol, inflammatory cytokines, and oxidative stress induce ER stress and activate the UPR chronically. The UPR activation is observed in a number of diseases including metabolic and inflammatory diseases, neurodegeneration, and cancer. The three UPR branches mediated by IRE1 α -XBP1, PERK-eIF2 α -phosphorylation-ATF4, and ATF6 α are important for tumor survival and growth under hypoxic conditions. IRE1 α and PERK also activate JNK and NF κ B to promote inflammation and apoptosis that contribute in inflammation in obesity and β -cell death in diabetes. PERK-mediated expression of CHOP contributes in aggravating diabetic states and atherosclerosis by exacerbating oxidative stress.

in cell homeostasis. Notably, pathological conditions, including metabolic disorders such as hyperlipidemia, hypercholesterolemia, hyperhomocysteinemia, hyperglycemia, inflammatory cytokines, and intracellular signaling such as the insulin anabolic response, pathogen infection, and tumorigenesis, all disrupt protein folding in the ER. Therefore, UPR activation is a hallmark of pathological conditions in human disease states, as well as in mouse models of human disease. Beside UPR activation, it was proposed that ER stress itself contributes to the pathology of many diseases (Schroder and Kaufman, 2005a; Kaufman, 2002; Wang and Kaufman, 2012).

The progress in the use of animal models of disease has greatly contributed to our knowledge regarding how the UPR impacts on normal physiology and disease pathogenesis. In addition, the identification of mutations in human genes often identifies or strengthens the casual relations between UPR defects and pathogenesis.

UPR Signaling May Contribute to Pancreatic β -Cell Degeneration and Diabetes

Pancreatic β -cell function is essential to maintain blood glucose homeostasis and its loss leads to diabetes, a chronic and degenerative disease. In normal individuals, high glucose stimulates insulin release from stored granules in β -cells and also increases proinsulin mRNA translation to replenish the pool of insulin granules. Circulating insulin stimulates glucose uptake in fat and muscle and reduces gluconeogenesis in the liver to maintain euglycemia. Therefore, proinsulin synthesis, folding and trafficking to secretory granules is coupled with insulin secretion in β -cells. Type 2 diabetes, i.e., adult onset, results from peripheral insulin resistance that increases levels of glucose, fatty acids, and inflammatory cytokines in the blood that can contribute to β -cell failure. Insulin resistance in fat and muscle causes the β -cell to increase insulin production. The increase in insulin production causes a load on the ER protein-folding capacity that is sufficient to initiate a series of events including proinsulin misfolding, insulin granule depletion, loss of glucose-stimulated insulin secretion, and oxidative stress leading to β -cell apoptosis (Laybutt et al., 2007; Huang et al., 2007).

The secretory function of β -cells depends on a functional UPR. The β -cell is unique because it is the only cell in the body that increases protein (mostly representing proinsulin) synthesis up to 10-fold upon glucose stimulation. As a consequence, several lines of evidence support the notion that the PERK-eIF2 arm is essential for β -cells to adapt to changes in protein synthesis (Harding et al., 2000b; Scheuner et al., 2001; Volchuk and Ron, 2010; Back et al., 2009). First, individuals afflicted with the autosomal recessive genetic disease called the Wolcott–Rallison syndrome require insulin at the age of 3 years. This syndrome is caused by loss-of-function mutations in PERK that cause β -cell failure. In addition, PERK deletion in mice recapitulates the β -cell failure observed in Wolcott–Rallison syndrome in humans (Harding et al., 2000b; Scheuner et al., 2001). Conditional deletion of PERK, i.e., deletion restricted to β -cells, further supports a homeostatic role for PERK in signaling β -cell survival (Cavener et al., 2010). In addition, mice with a Ser51Ala mutation at PERK phosphorylation

site in eIF2 α in a homozygous state, or in a heterozygous state combined with high fat diet, manifest β -cell loss due to proinsulin misfolding, ER stress, oxidative stress, and apoptosis (Back et al., 2009; Scheuner et al., 2005). Thus, PERK-mediated phosphorylation of eIF2 α is essential for normal β -cell physiology and loss of its function leads to β -cell failure and apoptosis and glucose intolerance.

β -cell failure in type 2 diabetes can also be exacerbated by pro-apoptotic components of the UPR, such as CHOP. Studies in mouse models of type 2 diabetes indicate that CHOP deletion not only protects β -cells from apoptosis but improves β -cell function by reducing oxidative stress and improving protein folding in the ER in diabetic *Akita* mice that express mutant Cys96Tyr misfolded proinsulin and in mice challenged with insulin resistance (Wang and Kaufman, 2012).

Other UPR components also contribute to the onset of type 2 diabetes. Inhibiting the IRE1 α -TXNIP axis by use of IRE1 α RNase inhibitors or deletion of *Txnip* reduces pancreatic β -cell death upon ER stress and suppresses diabetes in *Akita* mice (Lerner et al., 2012). Moreover, either deletion or increased expression of XBP1 in β -cells causes loss of β -cell homeostasis. β -cell specific XBP1 deletion in mice decreased the number of insulin granules, impaired proinsulin processing, blunted glucose-stimulated insulin secretion, and inhibited cell proliferation (Lee et al., 2011a). In addition, recent evidence suggests the defective IRE1 α and ATF6 α signaling accompany development of type 1 diabetes (Engin et al., 2014).

Additional recent findings point to a role for ATF6 α in protecting β -cells from ER stress. WFS1 (Wolfram syndrome 1 gene) encodes an ER transmembrane protein thought to regulate Ca⁺⁺ homeostasis. WFS1, a downstream target of XBP1s, is a negative regulator of ATF6 α and prevents β -cell death upon prolonged ATF6 α activation (Fonseca et al., 2010). Where mutations in WFS1 cause β -cell failure associated with Wolfram syndrome, polymorphisms in WFS1 are associated with impaired β -cell function and risk of type 2 diabetes (Sparso et al., 2008). In addition, some evidence suggests that ATF6 α variants are associated with type 2 diabetes (Wang and Kaufman, 2012). These findings provide a new link between ATF6 and protection from ER stress and β -cell death. However, ATF6 α deletion in the mouse did not dramatically interfere with β -cell function (Usui et al., 2012; Wu et al., 2007).

Metabolic Syndrome Activates UPR Signaling

Metabolic syndrome is associated with obesity, dyslipidemia (increase of circulating lipids), decrease of high-density lipoprotein (HDL) cholesterol, and hypertriglyceridemia that are often a cause of hypernutrition. The pathologies associated with metabolic syndrome are likely due to insulin resistance that develops when excessive lipids are deposited in insulin sensitive cells (hepatocytes and myocytes) instead than adipocytes, generating lipotoxicity. Accumulation of lipids in muscle generates insulin resistance, due to defective insulin signaling, with consequent inhibition of glucose uptake. In an effort to sustain hormone action, β -cells increase insulin production and this creates ER stress and β -cell death. The loss of β -cell function contributes to the onset of type 2 diabetes, that is, a complication in one-third of the patients afflicted with metabolic syndrome.

The increase in fatty acids or inability to oxidize excessive fatty acids, mainly a task of mitochondria, also causes lipid accumulation in the liver hepatocytes, called nonalcoholic fatty liver disease (Malhi and Kaufman, 2011). This pathology eventually gives rise to inflammation and fibrosis associated with nonalcoholic steatohepatitis and cirrhosis. Several reports provide evidence that the UPR is essential to maintain lipid homeostasis in the liver. Hepatic steatosis is alleviated by activation of UPR, as mimicked by overexpression of BiP, a downstream effector of the pathway. The UPR also inhibits activation of the cholesterol biosynthesis regulator SREBP-c and also improves glucose homeostasis (Kammoun *et al.*, 2009). Accordingly, selective inactivation of any single arm of UPR aggravated steatosis under pharmacologically induced ER stress, although it is not known whether this is due to increased hepatic lipogenesis or decreased lipoprotein secretion (Rutkowski *et al.*, 2008; Zhang *et al.*, 2011). Moreover, XBP1 liver-deleted mice manifest hypolipidemia, but neither hypoglycemia nor hyperglycemia suggesting that the regulatory role of XBP1 in hepatic metabolism is primarily to maintain lipid but not glucose homeostasis (So *et al.*, 2012). One study demonstrated that the IRE1 α /XBP1 pathway is essential to maintain functional levels of PDI, which is a cofactor for microsomal triglyceride transfer protein, to promote triglyceride assembly onto apolipoprotein B during assembly of very low-density lipoprotein (VLDL) (Wang *et al.*, 2012).

Finally, the discovery of cAMP responsive element-binding protein, hepatocyte specific (CREBH), a liver-specific transcription factor, for the first time provided a molecular link between ER stress and the innate systemic inflammatory response (Zhang *et al.*, 2006). CREBH expression is induced at a transcriptional level by inflammatory cytokines such as TNF, interleukin 1 β (IL-1 β), and IL-6. CREBH is similar to ATF6 α being an ER transmembrane transcription factor of the ATF family (Figure 1). In response to ER stress, CREBH traffics to the Golgi and is cleaved by S1P and S2P, as previously described for ATF6 and SREBP, to generate an N-terminal soluble bZIP transcription factor. The nuclear form of CREBH activates the expression of a subset of the acute phase response (APR) genes, including those encoding serum amyloid P component and C-reactive protein but has only minor effects on the induction of UPR genes. These studies highlight that ER stress can initiate a proinflammatory response. These findings are important because inflammation contributes to the atherosclerotic process and also to the pathogenesis of cardiovascular diseases, among which are complications associated with metabolic syndrome. The findings put ER function in a central position to coordinate metabolism with inflammation.

Further, CREBH is also a regulator of lipid homeostasis (Zhang *et al.*, 2011). CREBH was demonstrated to regulate hepatic lipogenesis, fatty acid oxidation, and lipolysis under conditions of metabolic stress and control the activity of a lipoprotein lipase regulating VLDL-triglyceride clearance in the plasma through up-regulation of its coactivator apolipoproteins C2, A4, and A5 and down-regulation of its inhibitor Apoc3. Consistently, nonsynonymous hypomorphic mutations in human CREBH are associated with severe hypertriglyceridemia in humans (Lee *et al.*, 2011b). Moreover, the UPR is activated during adipocyte differentiation, a crucial step in body weight gain. Both eIF2 α phosphorylation and splicing

of XBP1 mRNA were detected (Han *et al.*, 2013b). The IRE1 α -XBP1 axis is required for the expression of the key adipogenic factor C/EBP α . ER stress and UPR signaling appears to be a stimulus for adipogenesis.

The UPR Provides a Protective Role in Infectious and Inflammatory Disease

The UPR plays a role in pathogen infection and in the immune response. During viral infection IRE1 α and PERK are activated by the high-level expression of viral glycoproteins. Misfolded viral proteins induce transcription of BiP. Moreover, PERK and PKR-mediated eIF2 α phosphorylation is required to repress viral proteins synthesis, but viruses have evolved mechanisms to prevent the effect of eIF2 α phosphorylation to promote their replication (Cheng *et al.*, 2005). Every interferon resistant virus has evolved a unique and selective mechanism to bypass the inhibitory impact of PKR-mediated phosphorylation of eIF2 α , which is a major component of the interferon antiviral response.

Activated IRE1 α binds to TRAF2 and this complex recruits I κ B-kinase (IKK) that phosphorylates I κ B leading to its degradation and nuclear translocation of NF- κ B that induces the production of inflammatory cytokines. IRE1 α is important to integrate ER stress with inflammatory response signaling (Zhang and Kaufman, 2008). In addition, signaling through toll-like receptors can recruit TRAF6 to cause activation and subsequent degradation of IRE1 α , independent of ER stress (Qiu *et al.*, 2013).

The differentiation of B lymphocytes into plasma cells, that actively secrete high levels of antibodies during the humoral immune response, is coupled to expansion of ER and of the secretory pathway. In this process, XBP1s plays an essential role. In contrast, PERK-eIF2 α and ATF6 α arms are not required in differentiation of mature B cells into plasma cells (Zhang *et al.*, 2005).

UPR Signaling Provides a Double-Edged Sword in Cancer

Tumors result from a complex, multistep process involving progressive cellular degeneration and selection for cells that can propagate under unfavorable conditions. Recent studies suggest protein misfolding in the ER may be an initiating event in tumorigenesis (Nakagawa *et al.*, 2014). Due to poor vascularization, tumor cells proliferate under conditions of low oxygen and nutrients. As a consequence tumor cell proliferation requires active UPR signaling (Wang and Kaufman, 2014). Anaerobic metabolism prevails and pro-survival responses are activated in cancer cells.

Several studies support a role for the UPR in survival of cancer cells to extreme environmental stress (Clarke *et al.*, 2014; Wang and Kaufman, 2014). In particular, PERK-eIF2 α -ATF4 signaling pathway is critical under hypoxic conditions. The deletion of PERK, mutations that inactivate the kinase domain and phosphorylation-resistant forms of eIF2 α , all impair cell survival under hypoxic conditions. PERK also promotes cancer cell proliferation by limiting oxidative DNA damage through ATF4. Moreover, ATF4 is overexpressed in many solid tumors consistent with its role in regulating the expression of pro-survival genes.

The IRE1 α -XBP1 arm also contributes to growth and survival under hypoxia conditions. In a mouse glioma model, it has been shown that inhibition of IRE1 α reduces tumor growth and angiogenesis (Auf *et al.*, 2010). In addition, deletion of XBP1 increased sensitivity to hypoxia-induced cell death and reduced solid tumor formation (Fujimoto *et al.*, 2007). Moreover, since spliced XBP1 is essential for plasma cell differentiation, there has been interest to develop IRE1 α inhibitors for multiple myeloma, a cancer formed by malignant plasma cells. XBP1s is overexpressed in plasma cells derived from myeloma and this may be associated with the physiological role of XBP1s in promoting secretory functions during plasma cell differentiation. Thus, XBP1s may be a critical component in the induction of multiple myeloma. For this reason, studies have tested the therapeutic potential of IRE1 α RNase activity inhibitors (Papandreou *et al.*, 2011; Mimura *et al.*, 2012), although the results suggest a therapeutic benefit, there are concerns about general toxicity to other cell types. At present recommended treatment of multiple myeloma involves the use of proteasome inhibitors which induce death of multiple myeloma cells that accumulate misfolded immunoglobulin chains that cannot be degraded (Dimopoulos *et al.*, 2011). Unfortunately, resistance to proteasome inhibitors frequently occurs and this was associated with selection for cells that lose immunoglobulin expression and display preplasmablast characteristics (Leung-Hagesteijn *et al.*, 2013).

The studies of the role of the ATF6 arm of UPR in cancer are still limited but indicate that ATF6 α interacts with the other signaling pathways of UPR in promoting survival of tumor cells. Notably, ATF6 and XBP1 are responsible of up-regulation of BiP expression in hepatocarcinogenesis. Elevated expression of BiP is present in breast cancer, lung cancer, prostate cancer and other malignancies. The increase in BiP level plays a major role in pro-survival and cytoprotective response of cancer cells to environmental stress. The mechanism is through inhibition of apoptosis.

On the other hand, other studies indicate that alterations of UPR can also be involved in cellular apoptosis, inflammation leading to precancerous state especially in hepatocarcinogenesis. An indication is provided by single nucleotide polymorphisms in the ATF6 α gene that correlate with a decrease in ATF6 α mRNA and ATF6 α gene target contributing to hepatocellular carcinoma (Wu *et al.*, 2014). Moreover, *Chop*-null mutation promotes hepatic inflammatory gene expression and hepatic carcinogenesis. Thus, UPR can be involved also at the early steps of carcinogenesis (Dezwaan-McCabe *et al.*, 2013). Expression of BiP, a major ATF6 α target encoding an ER chaperone, not only correlates with cancer cell proliferation and histological grade, but also predicts response to therapies and prognosis (Pfaffenbach and Lee, 2011). Indeed, approaches to target BiP expression are under evaluation in the clinic (Rosenes *et al.*, 2013).

Targeting the UPR in cancer probably is a double-edged sword. On one hand, activation of the UPR is probably important in providing surveillance system to eliminate by apoptosis cells with mutations that might be oncogenic. On the other hand, tumor progression likely relies on UPR signaling to survive harsh conditions in the microenvironment. In conclusion, components of the UPR arms, including BiP and ERAD, are promising targets of new antitumor drugs. New

therapeutic strategies aim to exacerbate ER stress by inhibiting UPR and divert tumor cells from pro-survival to apoptotic pathways. Thus, the dualistic nature of the UPR may be exploited in developing new anticancer therapies (Wang and Kaufman, 2014).

UPR Activation Is Associated with Neurodegenerative Diseases

Whereas the role of the UPR in protein secretion and metabolic homeostasis is well characterized in nonneuronal cells, recent reports have documented a potential key role of the UPR in neuronal function (Wang and Kaufman, 2012). For example, XBP1 was recognized to regulate the induction of GABAergic markers to control the neurite growth. Translational control of ATF4 by GCN2-eIF2 α phosphorylation appears important for hippocampal synaptic plasticity and memory. eIF2 α phosphorylation appears required for learning and memory. Several studies document a requirement for protein synthesis for long-term potentiation (LTP) as well and mGluR1 long-term depression (LTD) (Costa-Mattioli *et al.*, 2007; Sidrauski *et al.*, 2013). Unlike LTD induced by stimulation of ionotropic glutamate receptors (N-methyl-D-aspartate receptor (NMDAR), LTD) induced by activation of metabotropic glutamate receptors (mGluRs) requires protein synthesis (Huber *et al.*, 2000). Alterations in mGluR-LTD have been linked to drug addiction, Alzheimer's disease, and intellectual disability (Luscher and Huber, 2010). Recent findings indicate that eIF2 α phosphorylation increases translation of selective mRNAs, one of which encodes OPHN1, a RhoGAP that stimulates synaptic vesicle endocytosis and is required for stabilization of dendritic spines (Di Prisco *et al.*, 2014). OPHN1 has two open reading frames within the 5' end of its mRNA that increase translation of OPHN1 upon phosphorylation of eIF2 α . Mutations in OPHN1 cause X-linked mental retardation in humans and its deletion in mice impairs spatial memory (Billuart *et al.*, 1998; Khelifaoui *et al.*, 2007). These studies suggest that inhibition of particular eIF2 α kinases may increase cognitive function.

All neurodegenerative diseases are associated with protein aggregation and UPR activation has been observed in a number of these diseases which include amyotrophic lateral sclerosis, Parkinson's disease, Huntington's disease, prion-related disorders, Alzheimer's disease, and demyelinating autoimmune diseases such as multiple sclerosis, retinal neuronal degeneration, and the list is not exhaustive. In particular, these studies have highlighted specific and even opposite effects of distinct UPR components, indicating that UPR importance in neurodegeneration depends on the disease context (see as a review, Hetz and Mollereau, 2014).

Where reduced eIF2 α phosphorylation may increase cognitive function, recent studies suggest that increased eIF2 α phosphorylation may reduce pathogenesis due to reduced synthesis of aggregation-prone proteins (Kim *et al.*, 2014; Ma *et al.*, 2013; Tribouillard-Tanvier *et al.*, 2008; Wang *et al.*, 2014). There is a need to identify under which conditions increased eIF2 α phosphorylation will increase cognitive function and those for which increased phosphorylation may reduce pathologies associated with expression of pathogenic

proteins. Importantly, inhibitors of GADD34 can protect from pathologies associated with protein aggregation associated with amyotrophic lateral sclerosis. Guanabenz is an antihypertensive agent that was shown to prevent pathogenicity associated with prion diseases and to inhibit GADD34 interaction with PP1 and prevent eIF2 α dephosphorylation, thereby reducing protein synthesis (Tsaytler *et al.*, 2011). Based on these findings, it seems that structural alterations to guanabenz to increase GADD34 interaction and reduce alpha adrenergic agonist activity may be encouraged.

Conclusions

The UPR is essential for the normal cell physiology and for adaptation to ER stress. The understanding of how the UPR intersects and cross-talks under normal conditions and in response to ER stress, and how ER function impacts other organelles is still the subject of intense research. Our increased understanding of the mechanisms that signal the UPR pathways has generated a wealth of knowledge, but there remain major unanswered questions. First and utmost, under what conditions is activation of any particular UPR signaling pathway beneficial or detrimental to any disease process? With an answer to this complex question, specific therapies may be envisioned for particular disease states, such as diabetes and cancer, and may provide in the future new strategies for other chronic and degenerative diseases. The dualistic nature of the UPR may be carefully explored to either inhibit the signaling to prevent cell death in response to ER stress or exacerbate it to prevent survival as in the case of tumor cells.

Glossary

A-lattice Microtubule lattice arrangement in a 3-start helix where protofilaments are effectively staggered by 4.9 nm. Beta-tubulin makes lateral contacts to alpha-tubulin at every protofilament–protofilament interface.

B-lattice Microtubule lattice arrangement where protofilaments are staggered by 0.9 nm. In a 13-protofilament 3-start helix, this results in a discontinuity at the seam. Perfect helical B-lattice microtubules can be formed from 15 protofilaments. A 13-protofilament 3-start helix with B-lattice arrangement is the usual conformation of microtubules found in most cells.

Catastrophe The transition from assembly (growth) to disassembly (shrinkage) at a microtubule end.

Dynamic instability Stochastic switching between phases of assembly and disassembly at microtubule ends.

Microtubule organizing center (MTOC) MTOC, such as the centrosome in animal cells or the spindle pole body in yeast, is the main focus of microtubule minus ends in the cell and point of highest nucleation activity.

Minus end Less dynamic end of the microtubule, embedded in the centrosome/spindle pole in most cells,

exposes alpha-tubulin or bound to gamma-tubulin ring complex.

Nucleation Initiation of *de novo* formation of microtubules occurs at a low rate by spontaneous aggregation of tubulin subunits, facilitated in cells by the gamma-tubulin ring complex, which has a 13-fold symmetry and acts as a template for the addition of alpha/beta-tubulin dimers.

Pause Term used for a state of little or no observable length change of a microtubule.

Plus end Dynamic end of a microtubule that grows faster than the minus end and exposes beta-tubulin.

Rescue The transition from disassembly (shrinkage) to reassembly (growth) at a microtubule end.

Seam Contact between the 13th and 1st protofilament in a B-lattice microtubule where neighboring protofilaments are offset by 4.9 nm instead of 0.9 nm as for the other protofilament–protofilament interfaces. This results in beta-tubulin making lateral contacts to alpha-tubulin at the seam.

+TIP or tip tracker Microtubule-associated protein that localizes to the terminal region of growing microtubules.

Microtubule Structure

Microtubules are dynamic polymers of 8 nm long, heterodimeric tubulin subunits that are formed by the non-covalent association of alpha-tubulin and beta-tubulin. Within the microtubule, tubulin dimers associate head-to-tail to form protofilaments,

which associate laterally into a tube of about 25 nm diameter (Figure 1). Microtubules with 13 protofilaments are most commonly found in cells, but 11- or 15-protofilament microtubules have been observed in specialised cell types in mammals and invertebrates (Chalfie and Thomson, 1979; Cueva *et al.*, 2012; Saito and Hama, 1982). Protofilaments are staggered by 0.9 nm

Figure 1 Microtubules are formed from alpha/beta-tubulin heterodimers. The most common arrangement is a B-lattice of 13 protofilaments that close into a tube. Microtubules assemble and disassemble at their ends. The plus end (exposing beta-tubulin) is more dynamic than the minus end. Microtubules show dynamic instability, switching from phases of growth to phases of shrinkage, an event called catastrophe. The reverse switch is a rescue. Dynamic instability is due to a cap of GTP-tubulin at the end of growing microtubules, which protects it from shrinking. Stick model of tubulin dimer (pdb accession 1SA0) shows non-exchangeable GTP (red) in alpha-tubulin and GDP bound to beta-tubulin (orange). Sites of posttranslational modifications at Lysine 40 in alpha-tubulin and a number of residues in the C-terminal tails of both alpha- and beta-tubulin are indicated.

or 4.9 nm, resulting either in beta-tubulin to laterally contact beta-tubulin (B-lattice) or beta-tubulin contacting alpha-tubulin (A-lattice). The most commonly found arrangement is 13-protofilament B-lattice microtubules with a seam between the 13th and 1st protofilament (Mandelkow *et al.*, 1986). All tubulin heterodimers are oriented with beta-tubulin pointing towards the plus end of the microtubule, therefore, the microtubule has intrinsic polarity and two different ends (Figure 1).

Tubulin is highly conserved in all eukaryotes and tubulin-related genes are expressed in bacteria. In vertebrates, the

tubulin gene family comprises 9 alpha-tubulin and 10 beta-tubulin genes (Khodiyar *et al.*, 2007; Huzil *et al.*, 2007). The highest variability between these tubulin isoforms is located within the C-terminal 15–20 amino acids. This negatively charged C-terminal tail of tubulin is further diversified by a number of posttranslational modifications (Figure 1). For example, the C-terminal tyrosine residue in alpha-tubulin is removed by a carboxypeptidase and added back by tubulin tyrosine ligase (Ersfeld *et al.*, 1993). Further modifications include the addition of polyglutamate and polyglycine side

chains to the C-terminal tail of alpha- and beta-tubulin and the acetylation of Lysine 40 on alpha-tubulin. Tubulin post-translational modifications occur on a subset of microtubules in cells and have been implicated in regulating the access of microtubule-associated proteins (MAPs) and motors to the microtubule. Specific modifications can either protect microtubules from depolymerizing enzymes, label them for destruction by severing enzymes or guide motor transport (Peris *et al.*, 2009; Lacroix *et al.*, 2010; Sirajuddin *et al.*, 2014). The details of this tubulin code and its implication in microtubule processes remain to be elucidated (See also Hammond *et al.*, 2008; Janke and Bulinski, 2011).

Microtubule Dynamics

Microtubules assemble and disassemble by addition and loss of subunits from their ends. The alpha-tubulin always contains a non-hydrolysable guanosine triphosphate (GTP), whereas the beta-tubulin contains a GTP molecule that can be hydrolyzed to guanosine diphosphate (GDP) during microtubule polymerization (Figure 1). It is the GTP hydrolysis in beta-tubulin that governs the dynamic switching between microtubule assembly and disassembly (Howard and Hyman, 2009; Mitchison and Kirschner, 1984). In the GTP cap model of dynamic instability, GTP-tubulin (i.e., tubulin with GTP bound at its exchangeable site in beta-tubulin) is incorporated at the growing microtubule end. Addition of the next layer of tubulin subunits accelerates GTP hydrolysis of beta-tubulin as the alpha-tubulin of the next subunit serves as GTPase activation protein (Nogales *et al.*, 1998). Therefore, the majority of the microtubule lattice is formed of GDP-tubulin with a small GTP cap at the growing end. This GTP cap stabilises the microtubule structure and keeps the microtubule in a polymerizing state. When the GTP cap is lost and GDP-tubulin is exposed at the microtubule end, a catastrophic depolymerization of the microtubule occurs. There are two models that explain the stabilising effect of GTP-tubulin. GTP hydrolysis generates mechanical strain in the microtubule lattice due to compaction at the nucleotide binding site (Alushin *et al.*, 2014; Hyman *et al.*, 1995). Loss of the GTP cap results in release of the strain by outward curling of the GDP-tubulin protofilament as seen for depolymerizing microtubules in electron micrographs (Mandelkow *et al.*, 1991). However, also GTP-tubulin has a curved conformation in solution and straightening occurs at incorporation into the microtubule lattice (Rice *et al.*, 2008; Nawrotek *et al.*, 2011; Buey *et al.*, 2006). Others have observed the nucleotide to affect the lateral interactions of tubulin subunits resulting in stronger, more difficult to break protofilament–protofilament interactions in GTP-tubulin lattices (Yajima *et al.*, 2012; Quiniou *et al.*, 2013).

While depolymerizing microtubules in cells and *in vitro* show predominantly frayed ends of the peeling protofilaments (Arnal *et al.*, 2000; Mandelkow *et al.*, 1991; Zovko *et al.*, 2008), the structure of growing microtubules is less clear. Electron microscopic observations suggest that microtubules grow as gently curved sheets that gradually close into the tube (Vitre *et al.*, 2008; Chretien *et al.*, 1995). However, many of these images are also compatible with tapered microtubule

ends, that is, incomplete microtubule lattice due to the different length of protofilaments. Tapered microtubule ends are in agreement with the variable decay of signal intensity at the ends of fluorescently labeled microtubules in cells and *in vitro* (Gardner *et al.*, 2011a; Coombes *et al.*, 2013).

At transitions between growth and shrinkage phases, the GTP cap is lost and regained. A microtubule will grow as long as the addition of new GTP-tubulin subunits is faster or equal to the rate of GTP hydrolysis. If assembly slows down, for example, if the microtubule is growing into a physical barrier such as the edge of the cell, GTP hydrolysis can catch up with the tip and the microtubule shrinks. This transition is called a catastrophe. The distribution of microtubule growth durations *in vitro* and in cells suggests that transitions through an intermediate state or the evolution of a more tapered tip structure occurs before catastrophe (Coombes *et al.*, 2013; Gardner *et al.*, 2011b; Odde *et al.*, 1995; Stepanova *et al.*, 2010). When a depolymerizing microtubule regrows, it is called a rescue. One idea is that GTP remnants in the microtubule lattice stimulate rescues (Dimitrov *et al.*, 2008).

Cellular Functions of Microtubules

Microtubules are the stiffest of the cytoskeletal filaments, 200-times stiffer than actin filaments when isolated (Gittes *et al.*, 1993). In crowded environments like the cytoplasm that restrict buckling, microtubules can bear very high compressive loads (Figure 2; Brangwynne *et al.*, 2006). Therefore, microtubules serve as structural elements in cells and can generate pulling and pushing forces. At the same time, microtubules provide the infrastructure for intracellular long-distance transport. Molecular motors of the kinesin and dynein family walk on the surface of microtubules to transport organelles, vesicles and molecular cargoes within the cell (Figure 2). In the case of a neuron, transport of neurotransmitters from the cell body to the presynaptic site requires covering distances in excess of 1 m. While single microtubules in the axon are on an average only 5 µm long, they are arranged in parallel bundles (Yu and Baas, 1994) to allow continuous motor-based transport.

In cells, the microtubule minus end is usually capped by gamma-tubulin and associated proteins, while the more dynamic plus end explores the intracellular space. The highest rate of microtubule catastrophe is observed at the cell edges (Komarova *et al.*, 2002; Drummond and Cross, 2000). This ensures that microtubule-based transport reaches the cell periphery. Furthermore, microtubule contacts with the cell cortex allow centering forces to be applied to the microtubule network (Figure 2). Such forces can be pushing of growing microtubule bundles against the cell tips as used for nuclear positioning in fission yeast (Tran *et al.*, 2001) or pulling forces mediated by cortically anchored dynein as used for spindle positioning in human cells (Samora *et al.*, 2011; Laan *et al.*, 2012). Coupling microtubule dynamics to subcellular structure allows harnessing forces mediated by polymerization and depolymerization (Figure 2). The segregation of chromosomes during

Figure 2 Microtubules and their associated proteins have a number of functions in cells. Being the stiffest cytoskeletal filaments, they carry high-compressive loads, especially when laterally reinforced. Microtubules serve as long-distance transport tracks, generate pushing and pulling forces, and act as signalling platforms and as templates for cellular self-organization.

mitosis is driven by coupling shrinking microtubules to kinetochores (Asbury *et al.*, 2006; Coue *et al.*, 1991), while polymerizing microtubule ends push membrane tubules of the endoplasmic reticulum (Waterman-Storer and Salmon, 1998; Grigoriev *et al.*, 2008).

The dynamic turnover of microtubules allows the rapid reorganization of the microtubule cytoskeleton into suitable arrays throughout the cell cycle and when cells change shape during cell locomotion or differentiation. Undifferentiated animal cells have a predominantly radial array of microtubules emanating from the centrosome. To form the mitotic spindle, microtubule nucleation is increased dramatically at mitotic entry, the two spindle poles separate and microtubules are stabilized upon contact with the kinetochores (Huitorel and Kirschner, 1988; Rieder, 2005; Snyder and McIntosh, 1975). Bundles of parallel microtubules fill the length of the axon. The minus ends of these microtubules are no longer embedded in the centrosome, but scattered throughout the cell (Yu and Baas, 1994). Acentrosomal microtubule arrangements are also commonly found in

muscle cells and polarized epithelia (Warren, 1974; Mogensen *et al.*, 2000). In plant cells, an antiparallel microtubule network lines the cell cortex (Hardham and Gunning, 1978). These specialized arrangements support cell polarity by allowing directional long-distance transport, serve as templates for the formation of higher-order structures such as the cell wall in plants and the sarcomers in skeletal muscle and act as structural scaffold to strengthen the cell axis (Figure 2; Paredez *et al.*, 2006; Pizon *et al.*, 2005; Franker and Hoogenraad, 2013).

Organelles are linked to microtubules to control their distribution in the cytoplasm. Examples for this are the distribution and dynamics of ER and mitochondria (Waterman-Storer and Salmon, 1998; Morris and Hollenbeck, 1995), ribosomes (Suprenant *et al.*, 1993) and the positioning of nuclei (Tran *et al.*, 2001; Metzger *et al.*, 2012). Microtubules probably also serve as signaling platforms as they bind and activate RhoGTPase regulators such as GEF-H1, STEF/Tiam and kinases such as Arg (Krendel *et al.*, 2002; Rooney *et al.*, 2010; Miller *et al.*, 2004). These molecules probably couple

Figure 3 MAPs are a structurally diverse group of proteins that either bind along microtubules (e.g., tau) or preferentially bind substructures on the microtubule such as the microtubule ends (e.g., EBs, CAMSAPs, and XMAP215). Other MAPs accumulate in microtubule overlaps (PRC1). MAPs modulate microtubule dynamics. They either induce catastrophe (e.g., kinesin-13s), cut the microtubule lattice to make two microtubules (severing enzymes), nucleate new microtubules (gamma-tubulin), or facilitate microtubule growth (e.g., XMAP215).

microtubule dynamics to signaling pathways controlling cell migration and shape changes (Figure 2; Kaverina and Straube, 2011).

MAPs

Microtubule dynamics, rigidity and functions are regulated by MAPs. MAPs can be split into two categories based on whether they bind to specific sites on the microtubule or decorate them along their length. The classic structural MAPs from the MAP2/tau family fall into the latter category. These MAPs recognize

the lattice of the microtubule and through their binding to more than one tubulin dimer often act as glue to stabilize the microtubule. Further lattice-binding MAPs are MAP4, Enscin/Map7, EMAPs and EMAP-like proteins, and GEF-H1 (Suprenant *et al.*, 1993; Chapin and Bulinski, 1994; Masson and Kreis, 1993; Krendel *et al.*, 2002; Rooney *et al.*, 2010). The second category includes MAPs that preferentially recognize specific features of microtubules or microtubule arrangements such as

- the microtubule plus end: XMAP215 family (Brouhard *et al.*, 2008)
- the microtubule minus end: gamma-tubulin (Li and Joshi, 1995); CAMSAP/Nezha/Patronin family (Meng *et al.*, 2008; Goodwin and Vale, 2010); Fidgetin (Mukherjee *et al.*, 2012)
- the assembly status of the microtubule end: growing ends – EB family and interacting + TIPs (Maurer *et al.*, 2012; Jiang *et al.*, 2012); shrinking ends – MCAK/Kif2C (Hunter *et al.*, 2003)
- bundles of microtubules: PRC1/Map65/Ase1 family (Gaillard *et al.*, 2008; Subramanian *et al.*, 2010; Liodice *et al.*, 2005); HSET/KifC1 family (Fink *et al.*, 2009; Braun *et al.*, 2009); Eg5/Kif11 (Kapitein *et al.*, 2005)
- microtubule crossovers: Katanin (Zhang *et al.*, 2013; Lindeboom *et al.*, 2013)
- regions of microtubule curvature: Doublecortin (Bechstedt and Brouhard, 2012)
- microtubule defects: Katanin (Diaz-Valencia *et al.*, 2011).

The ability to recognize specific structural features of microtubules is usually paired with the ability to specifically stabilize or destabilize the recognized microtubule substructure, enabling a multitude of ways how MAPs regulate microtubule structure, dynamics, and organization (Figure 3).

Regulation of Microtubule Structure and Mechanics by MAPs

MAPs control microtubule structure and rigidity. A number of MAPs are implicated in controlling the number of protofilaments. For example, in the *Caenorhabditis elegans* touch receptor neurons, the formation of 15-protofilament microtubules depends on the presence of alpha-tubulin acetyl transferase, the enzyme that acetylates Lysine 40 on alpha-tubulin in the lumen of the microtubule (Cueva *et al.*, 2012). 13-Protofilament microtubules are promoted through the action of doublecortin and EB1, both proteins localize between protofilaments and thereby constrain lateral tubulin interactions. In addition, both proteins track growing microtubule ends ensuring their presence at microtubule assembly (Fourniol *et al.*, 2010; Moores *et al.*, 2004; Vitre *et al.*, 2008; Maurer *et al.*, 2012; Bechstedt and Brouhard, 2012). Tau stabilizes microtubules and significantly increases their rigidity if added during microtubule assembly (Hawkins *et al.*, 2013). While tau still decorates the microtubule lattice of preformed microtubules, only copolymerization allows it to bind to sites in the microtubule lumen (Makrides *et al.*, 2004; Kar *et al.*, 2003). The tau-related, non-neuronal protein MAP4 does not

change microtubule rigidity, while MAP65-1 and Ase1 decrease rigidity (Hawkins *et al.*, 2013; Portran *et al.*, 2013). Thus binding to the microtubule lattice in itself does not stiffen the microtubule, but MAPs instead seem to modulate intradimer and interdimer distances to tune microtubule stiffness. Different microtubule stiffness could be of functional importance: In an environment such as a neuron, where microtubules play a structural role to support long and thin cellular processes, stiff tau-stabilized microtubules will be an advantage. In the microtubule spindle, formation of antiparallel overlaps in the spindle midzone by PRC1/MAP65/Ase1 requires bending of microtubules that encounter each other at high incident angles.

Regulation of Microtubule Dynamics by MAPs

Microtubule assembly and disassembly is regulated by an arsenal of cellular factors (Van der Vaart *et al.*, 2009). While some of those can be classified as microtubule stabilizers or destabilizers, there are a number of factors that have more complicated effects. Microtubule dynamics is usually described by four or five parameters: the speed of growth and shrinkage, the rates of catastrophe and rescue and the fraction of time spent in pause (Straube, 2011). Microtubule stabilizers, such as the lattice-decorating MAPs tau and MAP2, promote growth and rescue, prevent catastrophe and slow shrinkage (Drechsel *et al.*, 1992; Kowalski and Williams, 1993). All these parameter changes are compatible with MAP2/tau acting as glue to stabilize the contacts between tubulin dimers in the microtubule lattice. Microtubule destabilisers, such as stathmin-family proteins and kinesin-13s, promote catastrophe and prevent rescue by sequestering free tubulin dimers and inducing a curled protofilament conformation (Newton *et al.*, 2004; Steinmetz, 2007). Proteins of the chTOG/XMAP215 family accelerate microtubule assembly and disassembly in a catalytic manner. Thus depending on whether the reaction conditions favor assembly or disassembly, XMAP215 speeds up the addition or loss of tubulin dimers at the microtubule plus end, probably through stabilization of an intermediate state of tubulin assembly/disassembly (Brouhard *et al.*, 2008). At the same time transitions between growth and shrinkage are suppressed. In contrast, a number of proteins promote fast transitions between assembly and shrinkage. Among those are CLASPs and ACF7, factors that mediate the capture of microtubules at the cell cortex or kinetochores (Kodama *et al.*, 2003; Mimori-Kiyosue *et al.*, 2005). The mechanism of their action is less clear. CLASPs contain a number of microtubule-interacting domains and preferentially bind to a region about 1 μm away from the microtubule tip. Stabilizing the interaction of several neighboring tubulin dimers at its binding site could delay microtubule shrinkage and favor regrowth.

Minus end-capping proteins such as gamma-tubulin, ninein and members of the CAMSAP/Nezha/Patronin family stabilize the microtubule minus end and protect it from depolymerization (Goodwin and Vale, 2010; Li and Joshi, 1995; Meng *et al.*, 2008; Mogensen *et al.*, 2000). Microtubule dynamics is restricted to the ends of microtubules. However, severing proteins Spastin, Katanin and Fidgetin cut the microtubule lattice (Sharp and Ross, 2012). This generates a

new minus and plus end, respectively, on the two resulting microtubules. In addition to severing, Katanin has been shown to accelerate depolymerization from both microtubule plus ends, while Fidgetin is a minus end depolymerase (Mukherjee *et al.*, 2012; Zhang *et al.*, 2011). Thus the combined activity of severing and depolymerization can result in the rapid disassembly of microtubules unless the new ends recruit minus end-capping proteins or conditions favor microtubule assembly.

Especially when looking at proteins that track the growing ends of microtubules, the so-called +TIPs, understanding the exact contribution of each protein can be difficult due to the dynamic interactions of a large number of proteins in the +TIP complex. Depleting one factor can result in freeing up space for another factor. Therefore, depletion experiments provide potentially misleading information about the function of these proteins. Reconstitution of microtubule dynamics and tip tracking from purified components has proven to be powerful to study those proteins individually and the synergistic effects of combinations of proteins in a controlled environment. One of such examples is the interaction of end-binding proteins (EBs) and mitotic centromere-associated kinesin (MCAK). MCAK is a potent depolymerase inducing catastrophe and accelerating shrinkage. In cells, MCAK tracks growing microtubule ends via EB1 and EB3. Reconstitution of this module reveals that EBs promote robust growth phases even in the presence of MCAK, while the targeting to microtubule ends via EBs increases MCAK-mediated catastrophes (Montenegro Gouveia *et al.*, 2010).

Arrangement of Microtubules into Higher-Order Structures by MAPs

Microtubules are organized into suitable arrays by the cooperation of mechanisms that control nucleation, selective stabilization and destabilization, microtubule transport and sliding, bundling and crossbridging. Microtubules nucleated from centrosomes will result in radial arrays, therefore, parallel microtubule arrays with either uniform directionality or antiparallel arrangements are often formed by acentrosomal nucleation. Acentrosomal nucleation can occur free in the cytoplasm or by gamma-tubulin containing complexes residing on existing microtubules (Musa *et al.*, 2003; Petry *et al.*, 2013; Straube *et al.*, 2003). Microtubules can also be amplified by severing. Cutting a microtubule produces two microtubules with the same orientation. Thus a cycle of severing and assembly can very quickly lead to the amplification of microtubules of a certain orientation, a process that has been implicated in the light-induced reorganization of the cortical microtubule array in plants and microtubule reorganization events in meiotic spindles (Lindeboom *et al.*, 2013; McNally *et al.*, 2006).

While nucleation and severing will determine the initial position of the microtubule minus end, microtubules can be transported along other microtubules or the cell cortex. Motors implicated in microtubule sliding are dynein, kinesin-1, Eg5, and kinesin-14s (Straube *et al.*, 2006; Jolly *et al.*, 2010; Fink, 2006; Rusan *et al.*, 2002; Kapitein *et al.*, 2005; Tanenbaum *et al.*, 2013; Fink *et al.*, 2009). Force generated by microtubule

sliding is crucial for the initiation of neurite growth and microtubule fragments are transported into neurites where they extend into parallel arrays (Lu *et al.*, 2013; Yu *et al.*, 1996). Microtubules are locked into position by crosslinking proteins such as proteins of the PRC1 family, which preferentially bind and stabilize antiparallel overlaps. While we start to understand from reconstitution experiments how individual MAPs and motors function, there are only few studies thus far looking at the cooperation of two or more components. These revealed functional modules with interesting new properties. For example, PRC1 and kinesin-4 cooperate to keep antiparallel microtubule overlaps at a specific length (Bieling *et al.*, 2010). Likewise PRC1-homolog Ase1 shows adaptive breaking to prevent antiparallel overlaps from being slid apart completely by kinesin-14 motors (Braun *et al.*, 2011).

The selective stabilization or destruction of microtubules is another important mechanism to microtubule array organization. Selective stabilization often occurs when microtubules engage with the cell cortex or other subcellular structures, such as the kinetochore in mitotic cells. Microtubule capture limits microtubule dynamics to short length oscillations and serves to maintain long-lived contacts that allow cargo delivery to sites of capture, transduction of forces from microtubule assembly/disassembly to drive chromosome movements and the maintenance of a polarized, front-biased microtubule cytoskeleton in migrating cells (Kaverina and Straube, 2011; Asbury *et al.*, 2006; Straube, 2011). Attraction of severing enzymes to microtubules containing posttranslational modifications such as poly-glutamylation allows the removal of a subset of microtubules, while deetyrosination protects microtubules from depolymerization by MCAK (Lacroix *et al.*, 2010; Peris *et al.*, 2009). However, we still have to understand how selective modification and de-modification is regulated in cells. Modifications accumulate on microtubules that are stable and long-lived, but microtubule age cannot be the only factor as microtubules in the same cell can acquire different modifications and these tend to extend over the entire length of a particular microtubule.

Recent years have seen important advances in the techniques to study how complex assemblies of microtubules, MAPs and motors are formed and maintained while constantly turning over. These will in the next decade provide exciting new insights into cellular self-organization principles.

Microtubules in Human Disease

Microtubules are of central importance for cell division, cell morphology, and intracellular transport. Consequently, a number of diseases are associated with impaired microtubule function, most notably neuronal development defects, neurodegenerative disorders and ciliary dysfunction (Field *et al.*, 2014; Reiner, 2013; Bisgrove and Yost, 2006). Microtubule-targeting agents cause mitotic arrest and associated cell death, block cell migration and have vascular-disrupting properties. They are routinely used for the treatment of cancer and chronic inflammatory diseases and are in clinical trials for treating neurodegenerative diseases (Field *et al.*, 2014).

Actin Assembly Dynamics and Its Regulation in Motile and Morphogenetic Processes

J Pernier, P Montaville, and M-F Carlier, Cytoskeleton Dynamics and Motility Group, CNRS, Gif-sur-Yvette, France

Glossary

Barbed end and pointed end of the actin filament The polarity of the actin filament is visualized in electron microscopy by decoration with the motor domain of myosin. Myosin heads bind the side of each subunit making an angle with the axis of the filament that generates arrowhead structures, defining the 'barbed' and the 'pointed' ends. It has been established that the barbed end is the most dynamic (rapidly associates with monomeric actin, and rapidly disassembles), while the pointed end has slow dynamics.

Capping proteins Bind the filament end in a way that prevents association of G-actin and disassembly of F-actin. Most capping proteins act on barbed ends.

Focal adhesions Complex structures by which links are established between the extracellular substrate and the internal actin cytoskeleton of the adhering live cell. Focal adhesions are mechanosensitive, their size and molecular composition vary under tensile strength.

Isodesmic self-assembly A polymerization process defined by one single equilibrium reaction for formation of dimers, trimers, ... from monomeric units M , as follows:

$$K = [M_i] \cdot [M] / [M_{i+1}] = [M_i] \cdot [M_j] / [M_{i+j}]$$

Lamellipodia and filopodia Cellular extensions of the plasma membrane that adopt lamellar sheet-like or thin spiky morphology respectively, and are generated and maintained by actin assembly.

Persistence length of a polymer The length at which the polymer loses memory of its original tangential direction. The persistence length L_p is correlated to the stiffness S of the polymer, $L_p = S/k_B T$. The persistence length of standard F-ADP-actin filaments is 7–8 μm . It can increase up to 20 μm in the presence of tropomyosin, or in the transient F-ADP-Pi state of ATP hydrolysis.

Processive assembly of filaments Defines the function of formins, which remain individually bound to the barbed end of the polymerizing filament through many cycles of self-assembly.

Sequestering proteins Proteins that bind monomeric actin in a complex that cannot assemble in filaments.

Severing proteins Proteins able to fragment filaments, making them shorter without changing the mass of assembled actin in this process. At the molecular level, severing implies transient binding of the protein (or drug) to the side of one filament followed by a structural change that enhances the affinity of the protein (or drug) for the final state, which consists of two filaments. In the final state the severing protein is often bound to one of the two ends created by the cut. For instance gelsolin when added to a solution of F-actin, severs rapidly to remain very tightly bound to the barbed end created by the cut. This reaction is actually faster than direct binding of gelsolin to the existing barbed ends which are present at 4 orders of magnitude lower concentration than the sites along the side of filaments. Some marine-organism derived macrolides also act as filament severers. Some severers alternately strip off an actin subunit from the severed filament.

Stochastic optical reconstruction microscopy

(STORM) A light microscopy super resolution imaging method that emerged, together with related PALM (photoactivated localization microscopy) and FPALM (fluorescence photoactivation localization microscopy) in 2006. These methods, derived from the pioneering work Werner Heisenberg (1930) and in depth mathematical developments, enable localization of individual molecules with high precision (in the range of the nanometer) due to the high number of photons that are captured following photoactivation by laser illumination of single molecules labeled with a probe, capable of photoswitching between a brightly fluorescent and a dark state. Spatial resolution is determined by the square root of the number of captured photons before inactivation of the probe, which is the critical point in the method. Probes must have a high contrast ratio (i.e., fluorescence ratio before and after photoactivation) to minimize the background.

WASP Protein responsible for the Wiskott–Aldrich syndrome – A syndrome of X chromosome-linked recessive immune deficiency characterized by thrombocytopenia and eczema. Immune deficiency is linked to mutations that are found mostly in the N-terminal moiety of the WAS protein. WAS proteins form a family that all share the ability to bind actin and Arp2/3 complex and catalyze filament branching by the same molecular mechanism.

Introduction

Actin is one of the most abundant and conserved protein in the eukaryotic kingdom. First identified as one of the main

component and partner of myosin in muscle (Straub, 1942, 1943), actin is also present in all non-muscle cells, where it stands, together with microtubules and intermediate filaments, as one of the major polymers of the cell cytoskeleton.

The essential property of actin is to self-assemble into non-covalent, dynamic, helical, and polar filaments. The dynamic nature of actin self-assembly is at the origin of its biological function in cell migration, cancer cell invasion, cytokinesis, endo- and phago-cytosis, wound healing, immune response, synaptic plasticity and a large number of morphogenetic and axis patterning processes (Lauffenburger and Horwitz, 1996; Pollard and Cooper, 2009; Bugyi and Carlier, 2010; Salbreux *et al.*, 2012; Heisenberg and Bellaiche, 2013).

In contrast to microtubules, which, in animal cells, are organized in one major radial array from the microtubule organizing center (MTOC), actin filaments are engaged in various structurally and functionally different ‘modules.’ These structures develop elementary protrusive, adhesive, and contractile activities (Small *et al.*, 1996; Le Clainche and Carlier, 2008; Lammermann and Sixt, 2009), which are coordinated in more complex biological functions. In response to signals in particular through the small GTPases Rho, Rac and Cdc42, the actin cytoskeleton is remodeled rapidly, via local disassembly and site-directed nucleation-growth reactions, generating shape changes (Ridley *et al.*, 2003; Ridley, 2011; Hall, 2012; Chaki and Rivera, 2013). The dynamic architecture of the actin cytoskeleton thus enables the cells to move, feed, divide, interact with neighbors, and organize intracellular transport of particles. In the special case of plant cells which have no centrosome and possess a rigid wall, the cytoskeleton (both actin and microtubules) plays a role in shape maintenance, traffic, and cell growth.

Outstanding questions about how actin drives cell motility have attracted approaches from various disciplines from structural biology to cell biology and physics in the past 20 years. This article focuses on the following issues: What intrinsic properties of actin are at the origin of its functions? How are the nucleation and the assembly–disassembly dynamics of actin controlled? How do the molecular reactions that control actin assembly convert into macroscopic motile processes at the cell scale?

Actin: Structural and Mechanical Properties

Actin is a 42 kDa globular acidic protein, its structure is known at atomic resolution (Kabsch *et al.*, 1990). Actin is organized in four subdomains (Figure 1). The four subdomains define a cleft with subdomains 1 and 3 at the bottom of the cleft (actin barbed face), subdomains 2 and 4 at the top of the cleft (pointed face). ATP is bound in the cleft, in complex with a divalent metal ion (Mg^{++} under physiological conditions; Valentin-Ranc and Carlier, 1989). In low-ionic strength (non-physiological) conditions, actin remains monomeric (G-actin, standing for globular actin) due to repulsive electronegative interactions. At physiological ionic strength (0.1–0.15 M KCl, 1 mM Mg^{++}), repulsive forces are abolished and actin self-assembles in filaments (F-actin, standing for filamentous actin) that may contain thousands of subunits (370 subunits = 1 μm). The structural change linked to the G to F transition involves a propeller-twist movement of the outer and inner domains of the actin subunit around an axis roughly perpendicular to the filament axis, which makes actin flatter in the F state (Oda *et al.*, 2009; Figure 1(a)).

In agreement with the original atomic model of the actin filament (Holmes *et al.*, 1990) and the improved resolution structure derived from the fiber diffraction analysis (Oda *et al.*, 2009), the highest resolution structure of the actin filament in cryo-EM (Fujii *et al.*, 2010; Figure 1(b)) shows a polar helical structure in which assembled subunits are connected by a left-hand rotation of 167° and axial rise of 27.6 Å, describing the ‘genetic’ or short-pitch helix. The filament is also described as a two strand, right-handed, long-pitch helix that displays a crossover distance of 36 nm. The acidic N-terminal region of actin is exposed at the surface of the filament, accounting for its polyelectrolyte nature (Fujii *et al.*, 2010). Binding of positively charged ligands (cations, basic proteins, poly-L-lysine...) thus promotes association of actin filaments in rigid bundles (Tang and Janmey, 1996).

The highly ordered structure of actin filaments in very thin ice cryo-EM contrasts with the reported structural disorder in other electron microscopy observations, and the view that the structural disorder is used by regulators to generate multiple structural states and associated specified functions (Galkin *et al.*, 2003, 2010, 2011).

The structural organization of terminal subunits at the two ends of the filament may differ from the core subunits, since some of the filament actin–actin contacts are exposed to the solvent. How the potential structural plasticity of the terminal subunits is modulated by filament end-binding proteins is a timely issue. Only the structure of Capping Protein bound to barbed ends has been solved by combining crystallographic structure of free Capping Protein and cryo-electron microscopy images of capped filaments (Narita *et al.*, 2006). The cryo-EM structure of the pointed end (Narita *et al.*, 2011) reveals a tilted conformation of the terminal subunit toward the penultimate subunit, enhancing the strength of actin–actin contacts, thus accounting for the slow dynamics at this end. This structure has not been used so far in modeling pointed end binding proteins, but will be useful in understanding how proteins like tropomodulin associate with and regulate filament pointed ends. So far only crystal structures of isolated domains of tropomodulin in complex with monomeric actin are available (Rao *et al.*, 2014), from which a working model of tropomodulin bound to the pointed end is proposed. Similarly, the crystal structure of the FH2 domain of formin Bni1 in complex with actin is known, from which a working model is proposed for barbed end-bound formins (Otomo *et al.*, 2005), but no high-resolution cryo-EM structures are available for filament end-bound formins nor tropomodulin. However, often conclusions derived from crystal structures of complexes of monomeric actin with regulators do not match conclusions derived from functional or structural solution studies, due to drawbacks coming from crystallogenes conditions or crystal packing. The upcoming spectacular improvements in resolution brought by single detector camera in cryo-EM analysis of large macromolecular assemblies open a new age in relating structure and function.

Filaments can also be observed *in vitro* by negative staining electron microscopy (Figure 1(c)) and *in vivo* by cryo-electrotomography (Medalia *et al.*, 2007; Rigort *et al.*, 2012; Mueller *et al.*, 2014; Figures 1(d) and 1(e)), as well as using high-resolution STORM (Bates *et al.*, 2013; Xu *et al.*, 2012; Figure 1(f)).

Actin filaments are semiflexible polymers, i.e., their persistence length L_p is of the same order of magnitude ($8 \mu\text{m}$) as their average length (Isambert *et al.*, 1995). The flexural rigidity

of filaments is affected by bound ligands, reflecting the structural plasticity. Filaments are more rigid when tropomyosin or phalloidin is bound or when the filaments are made of

ATP-actin rather than ADP-actin subunits ($L_p = 18 \mu\text{m}$). In contrast, filaments are more flexible when ADF/cofilin is bound, ($L_p = 3\text{--}4 \mu\text{m}$), linked to a lower stability of actin-actin bonds in the filament (Carlier *et al.*, 1997, 1999; Pfaendtner *et al.*, 2010).

While filaments resist traction forces, they are easily fragmented by torsion (Yasuda *et al.*, 1996). Filaments are chiral polymers, not simple rods, hence it is possible that bending leading to severing, caused by either brownian motion or accessory proteins, affects the twist of the filament (Prochniewicz *et al.*, 2005; Matsushita *et al.*, 2012). In conclusion, the mechanosensitivity of actin, intimately linked to its structural plasticity, is at the heart of its multiple versatile functions in cell motility. It is used by several actin binding proteins. Additionally, protein machineries that couple actin filaments to membranes often are mechanosensitive and transduce mechanical force into biochemical regulation of actin dynamics. An interdisciplinary approach has actively developed in the recent years to understand the regulation of actin dynamics at a multiscale level.

Actin Self-Assembly: Nucleation-Growth, Thermodynamics, Polarity, ATP Hydrolysis

Bulk Solution Studies

The elementary helical unit of the filament is an actin trimer (Figure 1(b)). Consistently, spontaneous assembly triggered by a sudden increase in ionic strength is well described by a nucleation-growth process. The trimer is the smallest oligomer that shows a higher tendency to bind a 4th actin subunit than to dissociate (Wegner and Engel, 1975; Oosawa and Asakura, 1975; Korn, 1982). Nucleated self-assembly contrasts with the isodesmic self-assembly of linear polymers, described by a single type of interaction between subunits, leading to an equilibrium between monomers, dimers, trimers, and higher order oligomers.

The self-assembly of ADP-actin is well described by the laws of reversible polymerization (Oosawa and Asakura, 1975). Filaments grow faster at one end (the barbed end) than at the other (the pointed end). At the end of the polymerization process, actin exists in equilibrium between monomers

(ADP-G-actin) and filaments (ADP-F-actin) of several hundred subunits. The concentration of monomers at equilibrium with filaments is the equilibrium monomer-polymer dissociation constant $K_D = k_-/k_+$, called critical concentration for assembly, because actin remains monomeric below it. Filament fragmentation and re-annealing reactions also occur infrequently in F-actin solutions depending on filament number, length, and thermal brownian motion (Wegner, 1982; Schmolle *et al.*, 2011).

In nature, under physiological conditions, ATP is tightly bound to G-actin and is hydrolyzed irreversibly to ADP in a single turnover reaction following incorporation of an actin subunit in the filament, within two consecutive steps, cleavage of the gamma-phospho-ester bond followed by slower release of inorganic phosphate (Carlier and Pantaloni, 1986; Korn *et al.*, 1987; Murakami *et al.*, 2010). Although ATP hydrolysis is not required for polymerization, the assembly of actin filaments dissipates energy (as well as the assembly of microtubules from GTP-tubulin, which is associated with GTP hydrolysis). The fact that actin is an irreversible ATPase is pivotal in all its functions in cell motility (Carlier, 1989; Pantaloni *et al.*, 2001). Hydrolysis of ATP weakens actin-actin interactions in the filament. Due to the slow rate of Pi release, ATP or ADP-Pi is bound to terminal subunits at the rapidly growing end (barbed end) while ADP is bound to pointed end subunits, creating an energetic (stability) difference between the two ends of filaments. In ATP, filaments are thus maintained at a steady state – not at an equilibrium. A polarized flux of subunits through the filament, from the barbed to the pointed ends, called ‘treadmilling,’ describes the assembly dynamics of filaments both *in vitro* (Wegner, 1976) and *in vivo* (Lai *et al.*, 2008). A stationary concentration of ATP-G-actin allows the net flux of assembly at barbed ends to balance the net flux of filament disassembly at pointed ends (Wegner, 1976; Narita *et al.*, 2011). This process is highly regulated *in vivo* by proteins that bind differentially to the ATP- and ADP-bound forms of G and F-actin and by proteins that bind and affect the reactivity of either the barbed or pointed end, hereby affecting the rates of all elementary steps involved in the treadmilling cycle (Figure 2 and following sections).

Another mechanism differing from treadmilling, such as a sudden increase in G-actin availability, has been evoked to account for the observed growth of actin filaments in cellular

Figure 1 (a) Atomic structure of monomeric actin (G-actin-PDB code:1J6Z) and conformational change linked to its incorporation in a filament (F-actin PDB codes:3MFP) – local structural variability of actin monomer in the filament, adapted from Oda, T., Iwasa, M., Aihara, T., Maeda, Y., Narita, A., 2009. (c) Effect of capping proteins, enhanced rate of individual free barbed-end growth. (d) Graphic representation of the effects of ADF and capping proteins on treadmilling. Lines represent the dependence of the rates of filament elongation at barbed and pointed ends on the concentration of ATP-G-actin. The values of C_{ss} are C_{ss0} , which satisfy equal rates of barbed-end growth (r_1) and pointed-end disassembly (double headed arrow). Black lines: actin alone (characterized by C_{ss0} and r_0). Blue lines: the effect of 90% capping on the barbed-end kinetics (characterized by C_{ss1} and r_1). Red lines: effect of ADF on pointed-end kinetics (characterized by C_{ss2} and r_2). Purple lines: in the presence of both ADF and capping proteins (characterized by C_{ss3} and r_3).

processes. The monitored stationary rates of protrusion or pathogen propulsion in cytoplasm, for extended periods of time, argue against this mechanism, which would generate transient movements and exponentially slowing down of actin

assembly to arrest as observed in a test tube when G-actin is induced to polymerize at time zero. It is difficult to escape the view of a generalized regulated treadmilling mechanism to explain actin-based movements.

Single Filament Assembly Dynamics: Total Internal Reflection Fluorescence Microscopy

In the early 2000s, the use of evanescent wave microscopy allowed light microscopy observation of individual filaments growing from fluorescently labeled actin within a short distance (200 nm) from the coverslip, even in the presence of a large amount of labeled monomers in the chamber (Funatsu *et al.*, 1995; Kuhn and Pollard, 2005; Watanabe, 2012; Breitsprecher *et al.*, 2009). The method avoids the limitations due to the averaging of many filaments in bulk solution measurements. It is essential in monitoring processive assembly motors or the behavior of heterogeneous populations of filaments. Recent improvements of the standard total internal reflection fluorescence (TIRF) method have been brought by implementing microfluidics (Jegou *et al.*, 2011; Carlier *et al.*, 2014). Filaments are anchored at one end only at the surface of the coverslip, aligned with a microflow whose contents can be changed in 1 s, allowing kinetic studies. Molecular mechanisms by which proteins control filament assembly by binding barbed or pointed ends are addressed at the filament scale, and accurate statistical analysis of kymographs is greatly facilitated by alignment of filaments (Jegou *et al.*, 2011; Montaville *et al.*, 2014). The method thus represents the future of actin biochemistry at the single molecule level. Mechanical properties of actin filaments and of mechanosensitive protein machineries that control barbed-end growth such as formins is also addressed, using the flow to develop traction forces (Jegou *et al.*, 2013). Important future developments of this method are expected, as expressed in detail in perspective and review papers (Jegou *et al.*, 2011; Carlier *et al.*, 2014).

Regulation of Actin Assembly by Associated Proteins

A remarkable feature of the organization of the actin cytoskeleton is the specific set of actin regulators associated with each actin module within the cytoplasm. The mechanism underlying this functional and structural compartmentation is not fully understood. It is possible that site-directed nucleation of filaments by a given protein machinery directly recruits a set of associated regulators of the filament, or is linked to some signaling process that will impose a specific cascade of actin associated proteins binding in a cooperative fashion. The resulting exclusion of other sets of regulators may thus build a distinct composition/structure of a given actin meshwork. How different actin-binding proteins affect the structure and dynamic properties of actin individually and how they act in synergy or in antagonism provides insight into the emergence of biological complexity.

A general principle of the regulation of actin assembly by accessory proteins is based on their effect on the monomer-polymer steady state. Proteins that bind G-actin specifically displace the equilibrium toward the monomer and cause filament disassembly. Proteins that bind F-actin specifically displace the equilibrium toward the polymer. In addition to these simple cases, proteins bind the filament ends and affect their reactivity, i.e., modulate the rate parameters for actin assembly or disassembly at this end. Some proteins may also bind G-actin and not F-actin, but their complex with G-actin

may associate to filament ends with distinct rate parameters, hence they transiently interact with F-actin ends. Finally, some proteins may bind both G-actin and F-actin and change the dynamic monomer-polymer equilibrium.

The complexity of the regulation of actin assembly is enhanced when the regulators show some specificity for the ATP- or ADP-bound forms of G-actin and/or F-actin, or when they affect nucleotide exchange on G-actin. The relatively slow hydrolysis of ATP on F-actin acts as a timer that causes specific enrichment of old regions of the filaments in proteins that specifically bind ADP-F-actin, such as ADF/cofilin.

Some proteins are able to sever filaments. The severing mechanism implies that these proteins harbor two actin binding subsites, one on the side of filaments and one at the barbed face of actin, which enables them to strengthen their binding by cutting the filament and remaining bound to either the barbed end created by the cut (for instance gelsolin or Spire, 4 WH2 repeat protein), or to an actin monomer stripped off the filament (for instance Cordon-Bleu, a 3 WH2 repeat protein). Severing multiplies the number of filaments. Depending on the context, severing may either accelerate polymerization (as observed with Cordon-Bleu, which acts as a dynamizer of actin assembly in key developmental processes), or accelerate depolymerization and facilitate destruction of a complex filament meshwork.

Nucleation of actin filaments occurs mostly in a site-directed, signal-mediated fashion. Newly formed filaments often grow in a polarized fashion. Thus protein machineries which nucleate filaments often also bind their barbed ends to organize polarized growth. This is the case of formins and of proteins, which multiply rather than nucleate filaments by branching them (WASP family proteins, see following sections).

While a large number of actin regulators exhibit one of the above well-characterized individual activities, more recently discovered proteins display multifunctional regulation of actin assembly. These versatile regulators often combine several actin-binding modules of different functions (see Section 'The WASP Homology 2 (WH2) Domain: A Versatile Module').

Research on the regulation of actin assembly has been facilitated by the use of small molecules or drugs that mimic regulatory proteins, acting either by binding G-actin and preventing polymerization like thymosins, thus promoting depolymerization of filaments (Latrunculins: Spector *et al.*, 1983) or by binding G-actin as well as capping barbed ends (Cytochalasins) or stabilizing filaments abolishing dynamic turnover (phalloidin, jasplakinolide: Holzinger, 2001), or by slowing down dynamics (cyclic polyamines: Nedeva *et al.*, 2013). Chemicals also regulate actin dynamics by binding Arp2/3 complex (CK666: Nolen *et al.*, 2009; Hetrick *et al.*, 2013) or WASP proteins (Wiskostatin: Leung *et al.*, 2006) or formins (SMIFH2: Rizvi *et al.*, 2009).

The following sections illustrate the various modes of regulation of actin filament assembly dynamics by specific regulatory proteins.

G-Actin Binding Proteins

Proteins that bind specifically monomeric actin (Table 1(a)) may form a complex that either is non-polymerizable or displays polymerization properties that differ from G-actin.

Table 1 Main regulators of actin assembly

ABPs	Biochemical functions	Cellular localization	Regulators	Accession number
(a) G-Actin binding proteins				
b-Thymosins (Tß4,9,10,15) Ciboulot	Sequester G-actin	Blood, thymus, and hematopoietic cells brain	–	NP 066932.1 NP 066926.1 NP 068832.1 NP 919305.2
Profilins (three isoforms, profilin 1 most abundant and ubiquitous)	Promote actin monomer addition at barbed ends, enhance nucleotide exchange on G-actin, and enhance barbed-end depolymerization	Cytoplasm	PIP ₂	NP 005013.1 NP 444252.1 NP 001025057.1 NP 955378.1
WH2 domains	Sequester G-actin, may display profilin function, and also multifunctional regulators of barbed-end dynamics	Inserted in a large number of proteins involved in motile processes	–	NA (see Paunola et al., 2002)
ADF/cofilin Destrin Depactin Actophorin ADFH proteins: Drebrin Twintilin Abp1p coactosin	Bind ADP-actin specifically (both G- and F-actin)	Ubiquitous and essential	Lim kinase and Slingshot phosphatase	NP 005498.1 NP 006861.1 P20690.1 XP 003190377.1 NP 004386.2 NP 001229326.1 NP 010012.1 XP 009654332.1
Vitamin D-binding protein Gc globulin	Sequester G-actin	Plasma and cerebrospinal fluid	Vitamin D and C5A complement	NP 000574.2
(b) Barbed end-capping proteins				
Gelsolin	Severs actin filament	Blood, cytosol, and mitochondria	Calcium and PIP ₂	NP 000168.1

The former class of so-called G-actin sequestering proteins generates a reservoir of unassembled subunits in equilibrium with free G-actin. The stationary concentration of free G-actin in the cell, buffered by monomer-polymer exchange, thus determines the size of this pool. The important consequence is that any regulator of actin filament assembly that causes a decrease in critical concentration lowers the pool of sequestered actin; conversely, capping proteins which cause an increase in critical concentration, elevate the amount of sequestered actin and lower the concentration of F-actin (Carlier and Pantaloni, 1994). β -Thymosins (5 kDa), most abundant (200–400 μ M) in blood and hematopoietic cells, are major representatives of the G-actin sequestering proteins in vertebrates (Safer and Nachmias, 1994; Sun *et al.*, 1995). β -Thymosins bind specifically ATP-G-actin, very poorly ADP-G-actin (Carlier *et al.*, 1993).

The drug Latrunculin A binds G-actin on top of the ATP binding cleft at the pointed face of actin and is a major depolymerizing drug that acts like a sequestering protein (Ayscough, 1998).

Profilin (15 kDa) is another major, abundant G-actin binding protein that also binds ATP-G-actin preferentially. The profilin-actin complex productively assembles in filaments at the barbed end exclusively, with kinetic parameters similar to G-actin (Pollard and Cooper, 1984). Following association of profilin-actin complex to the filament barbed end, barbed end-bound profilin dissociates leaving the barbed end free for further association of actin or profilin-actin. The same regulatory mode is often adopted by a protein module called WH2 (WASP-Homology 2 domain, see Section 'The WASP Homology 2 (WH2) Domain: A Versatile Module'). Profilin lowers the steady-state concentration of ATP-G-actin

(Pantaloni and Carlier, 1993; Yarmola and Bubb, 2006). Profilin is generally essential in formin function *in vivo* (Sagot *et al.*, 2002; Manseau *et al.*, 1996).

Proteins of the ADF/cofilin family bind preferentially ADP-actin both in the monomer and polymer form (see section below).

Barbed End-Capping Proteins

These represent one of the most functionally important proteins in the regulation of actin assembly (Table 1(b)). Strong cappers generally bind exclusively filament barbed-end subunits with very high-affinity (K_d in the 10^{-9} – 10^{-10} M range) and block-filament growth and depolymerization. Several classes of strong cappers exist, among which proteins of the gelsolin family (brevin, severin, villin, CapG: for recent review, Nag *et al.*, 2013) and of the CapZ family (Capping Protein beta2; for review Cooper and Sept, 2008). Proteins that contain WH2 repeats, like Spire, may also work as barbed-end cappers. Capping of a large fraction of barbed ends in a population of filaments at steady state in ATP causes the amount of assembled F-actin to be controlled by pointed end dynamics only. The resulting increase in steady-state concentration of G-actin is amplified by sequestering proteins (Carlier and Pantaloni, 1994). Profilin becomes a G-actin sequesterer when all barbed ends are capped. Hence, capping proteins control the ratio of assembled and unassembled actin in cells. Barbed-end capping has to be highly regulated in cells. Proteins of the CARMIL family bind capping protein via a specific module called CPI (capping protein interaction) found in CapZIP, CIN85, CKIP-1, and FAM21, a subunit of the WASH complex, which controls capping protein allosterically and can uncap filament barbed ends. Myotrophin, in contrast, only sequesters capping protein (Hernandez-Valladares *et al.*, 2010; Takeda *et al.*, 2010). Regulation of Capping Protein by sequestration and uncapping is important since its cellular concentration is high (in the micromolar range in blood cells) while its optimum concentration in motility is at least one order of magnitude lower (Edwards *et al.*, 2014 for review).

Some proteins, like vinculin, present in focal adhesions, work as weak cappers, meaning that they bind weakly to barbed ends and only slow down barbed-end dynamics (Ramarao *et al.*, 2007).

The protein Eps8, which links signaling to actin, binds actin both on the sides of filaments with low affinity, inducing bundling, and caps barbed ends with high affinity (Disanza *et al.*, 2004), which supports its function in filopodia formation, synaptic plasticity, and intestinal morphogenesis.

The drug Cytochalasin D binds the barbed face of G-actin and thus causes F-actin depolymerization, however, in contrast with Latrunculin A, it also binds filament barbed ends with an affinity of 10^9 M $^{-1}$, and thus is a good tool as a substitute to capping proteins.

Barbed-End Trackers

Some proteins bind barbed ends specifically, but in contrast with cappers, they are permissive for filament assembly,

and regulate the reactivity (growth rate) of filament barbed ends by modulating the association rate constant of G-actin (Tables 1(c), 2(a), 2(b)). Their linkage to barbed ends may be more or less processive, that is the same molecule may remain associated with terminal subunits at the barbed ends through a variable number of consecutive steps of assembly or disassembly. Formins are the most remarkable representatives of this class of proteins. Formins are major regulators of nucleation and growth of actin filaments from profilin-actin in a large variety of motile and morphogenetic processes like cytokinesis, filopodia extension, which they mediate by site-directed assembly of several filaments associated in bundles (Goode and Eck, 2007 for review). Most formins actually catalyze processive filament barbed-end assembly at variable rates, which can be up to 10-fold faster than the standard rate of assembly at free barbed ends, the same molecule remaining bound to barbed ends for up to thousands of assembly rounds. Many but not all formins are also nucleators of filament barbed-end assembly; some formins nucleate only if associated to a ligand, for instance Bud6 affects nucleation of Bni1 and Bnr1 (Tu *et al.*, 2012). Formins are distributed in several classes, depending on their mode of regulation. A large number of formins (DRFs, standing for diaphanous-related formins), are regulated by membrane-bound small G-proteins of the Rho/Cdc42 family (Table 2(a)). The regulation of non-DRFs formins is less well known (Table 2(b)). Formins generally act in a site-directed fashion and maintain actively growing filament barbed ends attached to the membrane. The active moiety of formins comprises conserved formin homology domains 1 and 2 (FH1 and FH2) which bind profilin and actin respectively. Profilin is required for the *in vivo* function of most formins, and is required *in vitro* for fast processive growth (Romero *et al.*, 2004; Kovar *et al.*, 2006). The FH1 domain contains a variable number of proline repeats, which are thought to bind several profilin-actin complexes and bring them close to the barbed end (Paul and Pollard, 2008). However complexes of formins with a defined stoichiometry of profilin-actin have not been isolated. The processive property relies on the dimeric nature of formins. The FH2 domain crystal structure reveals a head-to-tail ring structure thought to embrace two terminal subunits at the barbed end (Xu *et al.*, 2004), which is supported by the structure of the FH2-actin complex (Otomo *et al.*, 2005). Processive tracking of barbed ends is suggested to be coupled to a cycle of transitions between two states of actin-bound FH2 at barbed ends (Goode and Eck, 2007 for review). In maintaining active polarized growth at filament barbed ends, formins antagonize barbed-end cappers and control the level of F-actin assembly at steady state accordingly. Formin rotation around the filament is associated with processive growth (Mizuno *et al.*, 2011). Finally, formins are mechanosensitive protein machines, which increase the rate of filament assembly when submitted to tensile forces of a few picoNewtons, compatible with the mechanical effects of membrane tension *in vivo* and forces involved in cytokinetic ring contractility (Jegou *et al.*, 2013).

Other barbed-end trackers include multimeric WH2 domain proteins such as Ena/VASP family of proteins and VopF/VopL (Pernier *et al.*, 2013). The exact molecular and structural mechanism of filament end-tracking is not well known.

Table 2 Diaphanous-related formins (DRFs) and non-DRFs

<i>Mammalian formins</i>	<i>Cellular functions</i>	<i>Intracellular localization</i>	<i>Cell type expression</i>	<i>Regulators</i>	<i>Accession number</i>

Pointed End Binding Proteins

These proteins (Table 1(c)) are less prominent than barbed-end cappers. Tropomodulin is a muscle protein that caps filament pointed ends while interacting with tropomyosin, thus regulating the length of actin filaments in skeletal muscle cells as well as in a variety of cell types (Yamashiro *et al.*,

2012). DNase 1 binds G-actin tightly at its pointed face, and can also cap filament pointed ends. Arp2/3 has been reported to cap filament pointed ends (Mullins *et al.*, 1998; Volkman *et al.*, 2014), but also to maintain barbed end dynamics in competition with capping proteins (Pantaloni *et al.*, 2001), which leaves a puzzling issue open regarding the mechanism of filament branching.

Proteins that Bind to the Sides of Actin Filaments

These proteins fall in several classes depending on their effect on the structure and related thermodynamic stability of the filament (Table 1(d)).

- a. Tropomyosin was originally discovered as a homodimeric, coiled coil muscle protein, however the appearance of tropomyosins in eukaryotes long predates the emergence of the muscle-specific isoform. In striated muscle, tropomyosin together with troponin regulates the acto-myosin crossbridge in a Ca^{++} -dependent manner. About 40 isoforms of tropomyosin, more than half of which cytoplasmic, are known and expressed in a tissue-specific manner (Gunning *et al.*, 2008; Wang and Coluccio, 2010). Tropomyosin is generally thought to stabilize filaments. It binds in the groove of the filament long-pitch helix, spans 4–7 actin subunits per molecule and thus strengthens actin–actin bonds in the filament. It competes and functionally antagonizes with other regulatory proteins like ADF/cofilin, which instead destabilizes the filament. The detailed effects of each isoform on actin assembly dynamics, the mechanism of isoform sorting, and how each isoform might recruit other specific regulators like Caldesmon and build up a complex regulation of actin assembly are unsolved issues.
- b. Because actin filaments are negatively charged polyelectrolytes, basic proteins bind and neutralize the exposed acidic N-terminal residues, promoting association of filaments in bundles. A large number of bundling proteins are known, including fascin, fimbrin/plastin, espins, alpha-actinin, and villin. Again several isoforms of all these proteins specify different actin higher order structures.
- c. Crosslinking proteins organize the actin meshworks in nonparallel bundles in various processes, often mediating their association with membranes and signaling pathways. These scaffolding, mechanosensitive proteins play essential roles in most morphogenetic processes, via elementary mechanisms that are not fully understood. Filamins are one prominent example (Razinia *et al.*, 2012). Other important scaffolds include spectrins and spectraplakins (Baines *et al.*, 2014; Suozzi *et al.*, 2012), cadherins (Budnar and Yap, 2013), proteins of the ezrin-radixin-moesin family (Neisch and Fehon, 2011), whose roles in essential motile processes are gradually emerging.
- d. Actin depolymerizing factor (ADF)/cofilin represents a family of conserved small (13–19 kDa) actin binding proteins (also called destrin, drebrin, etc...) that bind both G-actin and F-actin in their ADP-bound state specifically. Filaments made of ADF-ADP-F-actin are less stable than ADP-F-actin filaments (the critical concentration for assembly of ADP-actin is increased by ADF), the helical structure of the ADF-filament is modified (Bamburg *et al.*, 1999) and filaments fragment easily. In addition, the rate of nucleotide exchange on G-actin is greatly slowed down by ADF binding. In the presence of ADF, actin assembles in filaments that bind ADF as soon as P_i has been released following hydrolysis of ATP. The ensuing destabilization of the ‘aged’ ADF-ADP-F-actin stretches promotes partial depolymerization into ADF-ADP-G-actin, which accumulates up to a steady-state amount that depends on the

renewal rate of ATP-G-actin, that is on the concentration of ADF. The destabilization of F-actin by ADF correlates with enhanced rate of disassembly. In a population of treadmill filaments in ATP, pointed end disassembly of ADP-actin is the rate limiting process in the ATPase cycle. ADF accelerates this step 30-fold (Carlier *et al.*, 1997). Consequently, the measured steady state concentration of G-actin appears set to a higher level, which results in faster barbed-end growth. In other words, individual filaments treadmill faster in ADF. It is by enhancing depolymerization that enhanced barbed-end assembly occurs. Another view has been expressed according to which severing of filaments by ADF is responsible for their disappearance (Michelot *et al.*, 2007). It is worth noting that severing in itself only multiplies the number of filaments and does not cause faster depolymerization of individual filaments. Additionally, the proposed notion that treadmill is enhanced by severing is not sound at the scale of individual filaments. Severing can promote faster turnover of the mass amount of F-actin in solution, but each small filament is renewed at an unchanged rate. Thus this mechanism fails to explain ADF-enhanced barbed-end growth. This major regulatory activity of ADF/cofilin is observed *in vitro* (Carlier *et al.*, 1997) and *in vivo* (Lappalainen and Drubin, 1997; Kiuchi *et al.*, 2011). ADF is down regulated by phosphorylation of a conserved N-terminally located serine by LIM-kinase (Arber *et al.*, 1998). The phosphatase slingshot activates ADF by dephosphorylation (Niwa *et al.*, 2002). ADF, like profilin, is an essential protein in all actin-based motility processes including cell migration, endocytosis, and cytokinesis (Carlier *et al.*, 1999; Bernstein and Bamburg, 2010; Mizuno, 2013; Pfaendtner *et al.*, 2010).

The ADF Homology module (ADFH) is present in a variety of proteins (Drebrin, Abp1, and coactosin, which bind essentially F-actin, not G-actin) and sometimes duplicated like in twinfilin (Poukkula *et al.*, 2011). With two ADFH, twinfilin is able to cap and sever actin filaments, in addition to binding ADP-G-actin (Helfer *et al.*, 2006; Moseley *et al.*, 2006).

Another ADF-related protein is GMF (glia maturation factor), which binds specifically the ADP-bound form of Arp2 in Arp2/3 complex, thus enhancing the debranching of Arp2/3-branched filaments, regulating the plasticity of the meshwork (Gandhi *et al.*, 2010; Boczkowska *et al.*, 2013; Luan and Nolen, 2013).

The WASP Homology 2 (WH2) Domain: A Versatile Module

The WH2 domain (first identified in WAS proteins) deserves a special section because its functional versatility places it in a bunch of classes (Table 1(e)). The WH2 domain is a short protein module of about 20–30 amino acids. Intrinsically disordered in aqueous solutions, it folds upon binding to actin, adopting a binding mode similar to β -thymosins (Paunola *et al.*, 2002). Although they share with β -thymosins a binding mode supported by a short consensus LKKT ‘actin binding’ motif and a N-terminal amphipathic helix, WH2 domains display a vast sequence variability and are not evolutionarily related to β -thymosins. They are present, either as single motif or in tandem-repeated units, in several dozens of proteins which all play a role in motility. The WH2 domain

appears functionally versatile and becomes multifunctional when expressed as tandem repeats. It sometimes sequesters G-actin like β -thymosin, thus preventing actin assembly at both ends, and sometimes acts as a functional homolog of profilin, supporting filament barbed-end assembly specifically (Hertzog *et al.*, 2004). The change in function was dependent on the dynamics of interaction of the C-terminal stretch of WH2 with actin (Hertzog *et al.*, 2004). WH2 repeats were identified as nucleators of actin filaments (Quinlan *et al.*, 2005; Ahuja *et al.*, 2007; Tam *et al.*, 2007; Liverman *et al.*, 2007), but appear multifunctional regulators of filament barbed-end dynamics, spanning a range of activities from barbed-end capping (Spire) to barbed-end tracking and uncapping CP from barbed ends (Bosch *et al.*, 2007; Pernier *et al.*, 2013; Breitsprecher *et al.*, 2011; Hansen and Mullins, 2010; Khanduja and Kuhn, 2014; Co *et al.*, 2007). Moreover, Cordon-Bleu or Spire are potent filament severers (Husson *et al.*, 2011). In the cell context, where profilin competes with WH2 domains for binding actin and profilin-actin is the major monomeric form of actin, the WH2 repeats fail to nucleate filaments. Their multifunctional activities may correlate with their function in morphogenetic processes, brain development and adult brain functions involved in learning and memory, in which rapid filament remodeling is involved.

Site-directed Branching of Actin Filaments by WASP Protein Family and Arp2/3 Complex

In vivo, actin filaments are organized in a polarized fashion, with their elongating barbed ends facing the membranes. They are also generally initiated at specific sites by signal-responsive 'nucleators' (Campellone and Welch, 2010). Often nucleators are also regulators of filament barbed-end growth, thus they enforce site directed polarized growth of actin filaments, at the origin of force-producing processes (Chesarone and Goode, 2009). This is the case in lamellipodium and filopodium extension, in endocytosis, in Golgi trafficking, in focal adhesions, podosomes, in pathogen propulsion and maybe in cytokinesis and oocyte cortical actin organization.

A major way to nucleate new filaments in a site-directed fashion is harbored by WASP family proteins (Table 1(e)). These proteins are actual enzymes that use Arp2/3 complex to multiply filament barbed ends by branching, making two actively growing filaments from one, in an autocatalytic fashion. WASP proteins are activated by Rho family small GTPases using various mechanisms. They comprise many members, WASP in hematopoietic cells, neural (ubiquitous) N-WASP, WASH, WHAMM, WAVE, JMY (see Table 1), which all mediate formation of dendritic actin arrays in various cellular contexts, via the same molecular mechanism (Pollard, 2007). The association of WASP protein with proteins that recognize or induce membrane curvature (for instance BAR domains, Table 1(f)) specifies the type of membrane deformation resulting from site-directed dendritic array formation. Activation of WASP protein at the membrane exposes a C-terminal active domain called 'VCA' comprising a WH2 domain ('V,' sometimes a tandem repeat of WH2) followed by a connecting 'C' region and an acidic 'A' C-terminal short

stretch. The V region binds a G-actin molecule, the CA region binds Arp2/3 complex. Thus VCA bridges one G-actin and Arp2/3 complex. *In vitro* polymerization assays and microscopy imaging in cells (Mullins and Pollard, 1999; Svitkina and Borisy, 1999; Machesky *et al.*, 1999; Rohatgi *et al.*, 1999; Pantaloni *et al.*, 2000) showed that N-WASP used Arp2/3 to promote formation of branched filaments in an autocatalytic fashion. The 'branching complex' WASP-actin-Arp2/3 actually associates with a 'mother filament' to make a 'branch junction' in which Arp2/3 is incorporated and from which a 'daughter filament' is initiated and grows at the same rate as the mother filament. The detailed molecular mechanism of filament branching via this complex reaction is not understood (Rotty *et al.*, 2013 for review). The Arp2/3 complex is a highly conserved stable complex of seven subunits, including two actin-related proteins Arp3 and Arp2, and five ArpCs subunits (C1 to C5). The crystal structure of Arp2/3 complex is known at 2.9 Å resolution (Robinson *et al.*, 2001). Reconstitution of the full and partial complexes after expression of the seven subunits in insect cells provides insight into its structural organization (Gournier *et al.*, 2001). The cryo-EM structure of the branched junction is known at about 10 Å resolution (Rouiller *et al.*, 2008). The solution structure of the VCA-actin-Arp2/3 complex has been studied by SAXS (Boczkowska *et al.*, 2008). All these structures do not provide direct nonambiguous evidence for a unique mechanism of filament branching due to the limited resolution. Postulated structural changes of Arp2/3 upon binding VCA and filaments are required to accommodate the data. The upcoming advances in high-resolution cryo-EM are anticipated to elucidate the molecular mechanism of filament branching. Repeated cycles of filament branching by WASP using Arp2/3, G-actin and a filament as substrates, interrupted by filament barbed-end growth, generate a dendritic meshwork of branched filaments that promotes stationary propulsion of N-WASP-coated beads or vesicles in reconstituted motility assays (Wiesner *et al.*, 2003; Delatour *et al.*, 2008). The WASP protein remains immobilized at the bead/membrane during these cycles. Therefore, transient attachment of filaments in the branching process alternates with their growth, and maintains barbed ends constantly in proximity to the membrane during actin-based movement. This biochemical evidence supports the model of 'tethered ratchet' proposed by Mogilner and Oster for actin-based movement (Mogilner and Oster, 2003), and further developed recently to account for quantitative measurements of actin-based propulsion of the baculovirus (Mueller *et al.*, 2014).

The Arp2/3 complex, which is the substrate of WASP proteins, is in itself inactive in actin assembly. It can be sequestered by a variety of proteins (gadkin, arpin) which mimic the CA domain of VCA and in absence of the WH2 domain cannot elicit branching.

The plasticity of branched actin arrays is regulated by debranching, a reaction which is consecutive to hydrolysis of ATP on Arp2, and is enhanced by GMF, a protein of the ADF family that binds specifically to ADP-Arp2 in Arp2/3 complex (Gandhi *et al.*, 2010; Luan and Nolen, 2013; Boczkowska *et al.*, 2013). Debranching is also facilitated by coronin (Chan *et al.*, 2011), while cortactin in contrast stabilizes the branched filaments (Helgeson and Nolen, 2013).

Integrated Protein Modules in Reconstituted Actin-Based Motility

The principles of actin assembly dynamics and its regulation by essential actin binding proteins have led to successful reconstitution of self-organized systems showing production of force and movement by a minimal number of purified components (Figure 3). This achievement (Loisel *et al.*, 1999) validates the principle of regulated treadmilling at the origin of actin's function in motility. The two known actin-based self-organized motile systems (WASP-Arp2/3 and formins) generate movement using these principles. Indeed, in a reconstituted motility assay, like *in vivo* in lamellipodia and filopodia (Figure 3(a)), filament barbed ends elongate at a sustained rate, which implies that a constant concentration of polymerizable monomers is maintained in the solution. A sustained flux of depolymerization maintains this pool of monomers (Pantaloni *et al.*, 2001; Pollard and Borisy, 2003). The motility assay (Loisel *et al.*, 1999; Wiesner *et al.*, 2003; Romero *et al.*, 2004) reveals how molecular chemical reactions convert into macroscopic mechanical effects (Figure 3(b)). Only ATP as a source of energy is required for movement. The actin-based velocity displays a bell shape dependence on the concentration of the main players (Arp2/3 complex, ADF/cofilin, and capping protein), fully consistent with their biochemical properties (Carlier *et al.*, 1997, 1999). Specifically, depletion of Arp2/3 (by overexpression of the CA domain of WASP proteins or by Arp2/3 sequestering proteins using this motif) is predicted to slow down actin-based motility processes; conversely overexpression of Arp2/3 or increase in the density of branching by overexpression of N-WASP slow down actin-based motility, extensive branching of filament barbed ends competing with barbed-end growth.

Capping proteins are required for formation of the dendritic array and are inhibitory for formin-induced processive assembly (Wiesner *et al.*, 2003; Romero *et al.*, 2004), which was corroborated by *in vivo* observations (Mejillano *et al.*, 2004). The different optimum biochemical conditions for dendritic (WASP/Arp2/3 based) and linear (formin-mediated bundles) actin meshworks raise the issue of the mechanism that allows the coordinated function of these coexisting machineries in motile processes like lamellipodia or invadopodia (Figure 3(a)). Reconstitution and analysis of more integrated systems combining WASP- and formin-functionalized particles will provide answers to this issue.

In the future, more complex actin-based modules, like elementary focal adhesions, vesicularisation of Golgi tubules, endocytosis (Figure 3(c)), membrane-bound cortical actin arrays and their conversion to a cytokinetic ring should as well be reconstituted from a minimal number of actin partners, once the functional analysis of their individual components is completed. In many of these modules, actin assembly dynamics and force production are coupled to the dynamic and mechanical properties of the membrane. Linkage BAR-domain containing proteins that either sense or induce positive or negative membrane curvature are often associated with actin regulators (Figure 3(c)). These scaffold proteins, like IRSp53, CIP4/Toca-1, syndapin 1, MIM, ABBA-1, FBP17, bridge actin cytoskeleton and membrane by appropriate domains, and play essential roles in coupling membrane/vesicle recycling to

actin remodeling (Scita *et al.*, 2008; Suetsugu and Gautreau, 2012 for reviews).

The physical mechanism of force production against the membrane by directed assembly of actin filaments has been debated and several models have been proposed. In some physical models, it was argued that the mechanical properties of the dense actin gel were at the origin of the movement. Relaxation of the constraints resulting from insertional polymerization at the surface of a functionalized microsphere would exert a pressure causing its propulsion. The same view however cannot account for the production of a protrusive force like in lamellipodia, by the same chemical reactions and the same molecules. In addition, no relaxation of such constraints was observed in the propulsion of a vesicle (Delatour *et al.*, 2008). Finally, the observation that the baculovirus is propelled by site-directed growth and branching of less than a dozen filaments, with their barbed ends oriented toward the surface of the virus, a few of them attached to the surface (Figure 1(e)), indicates that the pushing force is directly produced by the growth of individual filaments rather than by the macroscopic elastic properties of an actin gel formed by intricated filaments (Mueller *et al.*, 2014). Microscopic models developed in closer relation with the observed chemical reactions that control movement include the brownian ratchet (Peskin *et al.*, 1993), followed by the tethered ratchet model (Mogilner and Oster, 2003) and the 'actoclampin' model (Dickinson and Purich, 2002) that actually preceded the experimental evidence for formin-promoted processive assembly (Pruyne *et al.*, 2002) or WASP-mediated barbed-end tracking (Hansen and Mullins, 2010). Progress in understanding the mechanism of actin-based motility requires detailed structural and biochemical studies of the elementary complexes formed between WASP, Arp2/3, and actin filaments during the cycle of branching, as well as between formin and the barbed end during processive filament elongation.

Finally, some motile processes, like translocation of the spindle in oocyte meiosis (Figure 3(d)), require actin assembly, but the detailed mechanism that leads to movement is not understood in detail. Progress is expected from high-resolution imaging, which now allows quantitation of the amounts of G-actin and F-actin *in vivo* (Figure 3(e)).

Actin Regulators in Adhesion Structures

Cells move by coordinated protrusion, adhesion, and contraction steps. Adhesion of cells to the ECM is strengthened by actin assembly, through maturation steps in which the chemical composition of the adhesive structures varies (focal complexes becoming focal adhesions) in association with regulatory phosphorylation reactions (focal adhesion kinase, FAK). A large number of proteins link extracellular matrix components to the membrane and the actin cytoskeleton (integrins, talin, and vinculin) and establish mechanosensitive coupling between the membrane and the actin cytoskeleton (Figure 3(a); see recent reviews Ross *et al.*, 2013; Wehrle-Haller, 2012). Focal adhesions are the archetype of structures transducing force into biochemical signals, in large part via actin assembly (Sheetz *et al.*, 2006; Schwarz and Gardel, 2012). However the detailed molecular mechanisms by which

Figure 3 Continued.

Figure 3 Continued.

nucleation and possibly processive assembly of actin filaments is regulated at focal adhesions is not yet understood in great detail and represents a challenge for the future. The biochemistry of cell adhesion will better be addressed in other articles.

Actin-Based Molecular Motors: The Family of Myosins

Myosins represent the archetype of molecular motors that associate with actin filaments in contractile structures in muscle but also in non-muscle cells (stress fibers). Myosins also organize intracellular traffic by translocating vesicles along actin filaments. The multiple functions of the many myosin families fall out of the scope of this article.

Actin in the Nucleus? Potential Role of Actin in the Regulation of Gene Expression

Actin is also an abundant component of the nucleus of amphibian oocytes, and plays a role in transcription of lampbrush chromosomes (Gounon and Karsenti, 1981; Scheer *et al.*, 1984). In somatic cells, most of actin is cytoplasmic, however the presence of actin in the nucleus – albeit in much lower amounts than in oocyte nucleus – has been detected (Egly *et al.*, 1984) and there too, actin in complex with actin-related proteins Arp4, Arp5, and Arp8 (Ino80) participates in remodeling of the chromatin (Visa and Percipalle, 2010; Grosse and Vartiainen, 2013). The molecular mechanisms involved in chromatin remodeling are still unknown. Whether

a monomer–polymer dynamic equilibrium of actin exists in the nucleus is elusive. Recent results suggest that nuclear F-actin assembly, revealed by the GFP-fused utrophin and LifeAct actin binding probes, occurs subsequent to signaling to transcription factors (Belin *et al.*, 2013). Since actin shuttles in and out from the nucleus, how the state of the large pool of cytoplasmic actin affects this equilibrium in the nucleus has to be clarified. Known actin regulators such as N-WASP, JMY, Arp2/3, formins mDia1 and mDia2, CapG and ADF/cofilin are present in the nucleus (Weston *et al.*, 2012) but in which actin-mediated processes they are involved is not clear. The MAL protein, an activator of the transcription factor SRF (serum response factor) is regulated by G-actin (Baarlink *et al.*, 2013; Treisman, 2013). MAL actually binds and sequesters G-actin via RPEL motifs, structurally and functionally similar to β -thymosins binding elements (Mouilleron *et al.*, 2008). Formation of the MAL–actin complex prevents nuclear import of MAL and activation of transcription. Consistently, an increase in F-actin leads to a decrease in sequestered nuclear G-actin, release of MAL, and activation of transcription (Baarlink *et al.*, 2013).

Bacterial Actin Ancestors

Actin-like proteins (Alps) have been identified in prokaryotes and archaea. Bacterial actins (MreB, AlfA, and ParM) show a high structural similarity with G-actin, but display highly divergent modes of helical assembly, as compared to the conserved eukaryotic F-actin. MreB assembles in single-stranded helical filaments, while ParM and AlfA assemble in a two-stranded polar helix like F-actin (Popp and Robinson, 2011 for review). In bacterial cells, the filaments arrange in bundles and cables, involved in bacterial shape building (MreB) or in plasmid segregation (ParM). Bacterial actins bind ATP or GTP in contrast with eukaryotic actin which selectively binds ATP. Nucleotide hydrolysis regulates the function of Alps.

Glossary

Astrocyte Star-shaped glial cell of the central nervous system.

Coiled coil Coiled coils are typically composed of two α -helices which consist of heptad repeats (abcdefg, where a and d are hydrophobic and e and f are charged amino acid residues) and are held together through strong hydrophobic interactions.

Cytolinker Protein connecting cytoskeletal filaments to each other and to cellular organelles.

Cytolysis Cell rupture.

Intermediate filament Cytoskeletal filament with a diameter of about 10 nm between that of actin filaments and microtubules.

Keratinocyte Predominant cell type in the epidermis.

The Intermediate Filament Protein Family is Subdivided into Six Types with Cell Type-Specific Expression Patterns

The members of the mammalian intermediate filament protein family are classified into six types based on sequence homology, gene organization, net charge, assembly mechanism, and expression pattern (Table 1; Coulombe and Wong, 2004; Herrmann *et al.*, 2009).

More than 50 type I and type II keratins comprise the 'soft' cytokeratins that are expressed in epithelial cells and the 'hard' keratins found in hair and nails. They are among the most abundant cellular proteins. Equal amounts of the more acidic type I and more basic type II keratins assemble into intermediate filaments in tissue- and differentiation-specific combinations. For example, the type I keratin 18 together with its type II partner keratin 8 is expressed in simple, one-layered epithelia of the intestinal mucosa, endometrium, or exocrine glands. In some of these epithelial cells, for example, hepatocytes, they are the only keratins expressed. In multilayered epithelia, such as the epidermis, other keratin pairs are expressed with specific keratin pairs in the basal cell layers (keratins 5 and 14) and suprabasal cell layers (keratins 1 and 10).

The type III intermediate filament proteins include vimentin, which is typically expressed in cells of mesenchymal origin such as fibroblasts, leukocytes, and endothelial cells, whereas desmin and syncoilin are found in muscle cells. Glial fibrillary acidic protein (GFAP) is produced in glial cells. Peripherin is mainly detected in peripheral neurons and in central nervous system neurons, which have projections toward the peripheral nervous system.

The type IV low-, middle-, and high-molecular weight neurofilament proteins NF-L, NF-M, and NF-H, whose C-termini differ dramatically in length, are highly expressed, together with α -internexin, in axonal processes of central nervous system neurons. Neurofilaments co-assemble *in vivo* as heteropolymers of NF-L and either NF-M or NF-H, respectively. Synemin, which is produced in glial astrocytes and muscle cells, and nestin, which is synthesized in developing and regenerating cells of the central nervous system and myogenic tissue, do not assemble into intermediate filaments on their

own but have regulatory functions for the assembly and disassembly of other intermediate filaments.

The type V lamin intermediate filament proteins are localized in the nucleus. At least one B-type lamin (B1, B2, and B2 splice variant B3) is expressed in every nucleated cell whereas A-type lamins (lamin splice variants A and C) have a more restricted distribution and are absent during early embryogenesis. Lamins are the major components of the nuclear lamina, a layer subjacent to the inner surface of the nuclear envelope.

Filensin and phakinin make unusual beaded filaments that are solely expressed in lens fiber cells.

Intermediate Filament Proteins Are Reliable Markers of Cellular Differentiation

The cell type-specific expression of intermediate filaments is exploited in tissue and tumor diagnosis (Moll *et al.*, 2008; Bragulla and Homberger, 2009; Karantzis, 2011). It is well

Table 1 The intermediate filament protein family is subdivided into six types with distinct distribution patterns

Type	Members	Distribution
I	'Acidic' keratins	Epithelial cells
II	'Basic' keratins	Epithelial cells
III	Vimentin	Mesenchymal cells
	Desmin and syncoilin	Muscle cells
	Glial fibrillary acidic protein (GFAP)	Glial cells
	Peripherin	Neurons
IV	Neurofilament proteins (NF-L, NF-M, and NF-H) and α -Internexin	Neurons
	Synemin	Astrocytes and muscle cells
	Nestin	Developing and regenerating cells
V	Lamins	Nuclear lamina of all nucleated cells
VI	Filensin and phakinin	Lens fiber cells

Figure 1 Model of intermediate filament protein structure. The central α -helical rod domain is subdivided into segments 1A, 1B, 2A, and 2B by non-helical linker domains L1, L12, and L2. The rod is flanked by the highly variable N-terminal head and the C-terminal tail domain. Type V intermediate filament polypeptides differ from Types I–IV by a 42 amino acid insertion in coil-domain 1B (star) and by a nuclear localization signal and immunoglobulin-like beta fold in the tail domain.

established that cellular differentiation is reflected by specific intermediate filament proteins. The main tissue types can thus be distinguished on the basis of their intermediate filament composition: epithelia are characterized by keratins, connective tissues by vimentin, muscles by desmin, and nervous tissues by neurofilaments in neurons and GFAP in glial cells. Intermediate differentiation states usually go along with defined admixtures of intermediate filament proteins. For example, myoepithelial cells contain desmin together with keratins or myofibroblasts vimentin together with desmin. In addition, further classification of tissue differentiation is possible by analysis of intermediate filament protein isotype combinations. This is especially true for the abundant epithelial keratins. Changes of differentiation, which occur during development or as a reaction to various insults, are also reflected by changes in intermediate filament expression. Taken together, the intermediate filament composition of a given cell can be taken as a reliable molecular marker of its differentiation and activity status. Remarkably, the same holds true for tumor cells. Epithelium-derived carcinomas are generally characterized by keratins, whereas mesenchymal tumors continue to produce vimentin. Furthermore, specific keratin pairs may provide clues for the origin of a given carcinoma and its differentiation status. Thus, simple epithelium-derived adenocarcinomas produce keratins 8 and 18, whereas multilayered epithelium-derived squamous cell carcinomas synthesize other keratin pairs, which are typical for multilayered epithelia. Changes in differentiation, however, which usually occur during malignant transformation and accompany dedifferentiation go along with alterations in intermediate filament protein expression. A prominent example is epithelial to mesenchymal transition, which is paralleled by dramatic shape changes and increased motility of invading cancer cells. These cells start to co-express vimentin together with reduced amounts of keratins.

Intermediate Filaments Share a Common Secondary Structure

Despite the sequence diversity among intermediate filament proteins they all share a common tripartite secondary structure

(Figure 1; Herrmann *et al.*, 2009): a ~ 45 nm-long α -helical rod domain is flanked by non-helical N-terminal head and C-terminal tail domains. The central rod domain is highly conserved and consists of four α -helices (coils 1A, 1B, 2A, and 2B) with interspersed non-helical linkers (L1, L12, and L2). Lamins carry an additional 42 amino acid insertion in the first central helical subdomain. The head and tail domains differ considerably in size, sequence, and secondary structure between different intermediate filament polypeptides. While the tail domain of human keratin 19 contains only 15 amino acids, nestin has more than 1300.

The rod domains interact with each other to form filaments, whereas the head and tail domains bind to various cytoplasmic elements including other cytoskeletal components. The N-terminal head domain regulates intermediate filament protein assembly, while the C-terminal tail domain is dispensable and only affects filament stability.

The amino acid sequences at the beginning and the end of the rod domain are evolutionarily most highly conserved. They are referred to as the helix initiation and helix termination motifs and are genetic hotspots for mutations in many hereditary intermediate filament disorders.

Intermediate Filaments Can Be Assigned to Three Different Assembly Groups

The initial building block of all intermediate filaments is the parallel, in-register, two-stranded coiled-coil dimer whose α -helices are strongly bound to each other by non-covalent hydrophobic forces (Figure 2). However, there are no crystallization data of polymerized full-length intermediate filament proteins available. Since the entire rod domains could not be crystallized, several rod fragments were analyzed. Coil 2B forms dimeric complexes while coil 1A remains monomeric in solution even at high protein concentrations although it assumes the helical twist that is necessary for coiled-coil formation (Strelkov *et al.*, 2002).

Depending on the subsequent mode of assembly intermediate filaments can be assigned to three different assembly groups (Figure 2; Herrmann *et al.*, 2009).

Figure 2 Schemes depicting major stages of intermediate filament assembly. Assembly groups 1 and 2 are characterized by parallel, non-staggered dimers consisting either of obligatory heteropolymers (assembly group 1) or facultative homopolymers (assembly group 2). Two antiparallel dimers associate in a staggered fashion to form a tetramer. Six to ten tetramers associate laterally into ~60 nm-long unit-length filaments, which elongate longitudinally and compact as 8–12 nm intermediate filaments. Nuclear lamins are members of assembly group 3. They also form polar, non-staggered dimers. However, dimers attach head-to-tail to generate protofilaments. Association of protofilaments occurs antiparallel to generate apolar intermediate filaments. Amino-termini (NH₂) and carboxy-termini (COOH) are labeled.

Type I and type II keratins belong to assembly group 1. Keratins are obligatory type I-type II heterodimers. Two antiparallel-oriented dimers associate laterally into staggered tetramers. The resulting lack of polarity of this and all further assembly intermediates is one of the distinguishing features of cytoplasmic intermediate filaments in comparison to the polar actin- and tubulin-based filament systems. Lateral association of 6–10 tetramers forms short ~60 nm unit-length filaments (ULFs) with a diameter of 8–16 nm. ULFs then anneal longitudinally giving rise to longer filaments that subsequently undergo radial compaction yielding 8–12 nm mature intermediate filaments. Keratin filament assembly is extremely fast and occurs spontaneously in physiologic salt solutions without any cofactors.

Assembly group 2 includes type III and type IV intermediate filaments, which typically assemble from homodimers. Further assembly intermediates are comparable to those found in assembly group 1 but may differ with respect to the number of subunits per filament cross section. In addition, the assembly rate is much slower than that observed in group 1.

The type V lamin intermediate filaments belong to assembly group 3. Lamins have a large C-terminal globular domain that contains an immunoglobulin-like beta-fold together with a nuclear localization sequence. Lamin dimers associate head-to-tail into polar protofilaments with protruding globular C-termini. Protofilaments then further associate laterally in an antiparallel fashion into extended ~10 nm mature apolar fibrils.

Figure 3 Intermediate filament network organization in murine tissues. The immunofluorescence micrographs depict the organization of keratins in hepatocytes of murine liver (a) and in a cross section of epithelial crypts of the intestinal mucosa (b). Note the enrichment of filaments around bile canaliculi (arrows) in liver and the subapical concentration of keratins in the epithelial cells surrounding crypt lumina (stars).

Intermediate Filament Networks Have Distinct Properties That Render Them Different from the Other Cytoskeletal Systems

Intermediate filaments differ in many aspects from the actin- and tubulin-based cytoskeletal filaments (Coulombe and Wong, 2004; Chou *et al.*, 2007; Herrmann *et al.*, 2009).

- Biochemically, intermediate filaments are difficult to solubilize. High concentrations of chaotropic reagents are needed to dissociate the extremely stable coiled-coil dimers.
- Intermediate filaments are apolar fibrous structures, which cannot guide motor protein-driven directional transport.
- Intermediate filament assembly occurs spontaneously in physiological salt solutions and does not require nucleotide triphosphates or proteinaceous cofactors.
- Intermediate filaments do not only elongate by addition of subunits to either end but also grow by incorporation of subunits along their entire length. Consistently, subunits can also dissociate from intact filaments. The process is referred to as ‘dynamic subunit exchange’ and results in considerable filament width inhomogeneity.
- Intermediate filament networks are very stable and retain their arrangement even when cells are treated with highly concentrated salt solutions and nonionic detergents.
- Intermediate filament proteins have a long half-life of up to several months. On the other hand, intermediate filaments have been shown to be dynamic. Based on high-resolution time-lapse imaging of cells transfected with fluorescently tagged keratin a model for the keratin filament turnover cycle was described (Windoffer *et al.*, 2011). Keratin filament precursors are formed in the periphery near the cell membrane where they assemble. They subsequently integrate into the existing filament network by moving inward. Near the nucleus filaments bundle and become either part of the perinuclear cage or dissolve and diffuse back toward the periphery where a new cycle is initiated starting with the formation of keratin filament precursors.
- The intermediate filament network provides compliance to small deformations on one hand and strengthens cells on the other hand when large deformations are applied. *In vitro* assays have shown that intermediate filaments are much more deformable than the other cytoskeletal

Figure 4 Electron microscopy of keratin intermediate filaments in epidermal cells. The micrograph in (a) depicts thick bundles of keratin (stars) connecting multiple desmosomes (D). M, mitochondrion; N, nucleus. The image in (b) shows a cytoplasmic region with thick intermediate filament bundles (stars) that are part of the highly interlaced three-dimensional cytoskeletal network. Images were kindly provided by Sabine Eisner.

filaments and can be stretched several times their initial length before they tear (Kreplak *et al.*, 2005). Upon application of force the filaments become more viscoelastic, a behavior that is referred to as strain stiffening (Janmey *et al.*, 1991).

Cytoplasmic Intermediate Filament Network Organization Is Determined by Interaction with Major Cellular Components through Associated Proteins

Intermediate filament networks present many different types of spatial arrangement. They form dense bundles of closely packed filaments in neuronal axons, they are part of a complex anchoring structure of Z-discs to the plasma membrane in striated muscle, they are concentrated in cortical compartments of hepatocytes, they are enriched subapically in enterocytes or make up a 3D-meshwork in epidermal keratinocytes (Figures 3 and 4). The molecular basis of the different organizational forms is still poorly understood. But the linkage of intermediate filaments to each other and to various other

determinants of cellular architecture including microtubules, actin filaments, and adhesive complexes at cell membranes, and to cellular organelles such as mitochondria, Golgi apparatus, endoplasmic reticulum, and the nucleus certainly contribute to it. These interactions are mediated by intermediate filament-associated proteins many of which contain a plakin domain (Sonnenberg and Liem, 2007; Bouameur *et al.*, 2014). A prominent plakin family member is the 500 kDa protein plectin with its multiple splice variants containing different binding modules (Wiche and Winter, 2011). This ubiquitously expressed and multifunctional cytolinker integrates the intermediate filament system into the cytoskeleton and connects it to other cellular components thereby affecting cell shape, tissue stability, and cell migration. The cytolinker function of plakins is particularly evident in epithelial cells, which are attached to each other by desmosomal cell–cell contacts and to the basement membrane by hemidesmosomes. Plectin has been localized to hemidesmosomes, whereas the plakin desmoplakin is present in desmosomes. In electron micrographs both structures are characterized by electron-dense plaques at the cell membrane with associated keratin intermediate filament bundles (Figure 4(a)). In this way forces are evenly distributed throughout the epithelial layer and propagated to the underlying connective tissue providing mechanical coherence and resilience.

Other intermediate filament-associated proteins have been identified with distinct functions for network organization. For example, filaggrins promote keratin filament bundling in epidermal cells. In muscles the intermediate filament type IV protein synemin, which does not form filaments on its own, integrates into existing intermediate filament networks through polymerization with vimentin and desmin type III intermediate filaments. Synemin recruits these mixed intermediate filament networks to extracellular matrix adhesion sites by interaction with focal adhesion components (Bellin *et al.*, 2001). In heart muscle, synemin thereby helps to distribute forces by attaching the contractile apparatus to the surrounding connective tissue.

Lamin Intermediate Filaments Contribute to Nuclear Structure and Function

The nuclear lamina of most mammalian somatic cells contains A- and B-type lamins, which form separate but interacting meshworks (Dechat *et al.*, 2008; Burke and Stewart, 2013; Zwerger and Medalia, 2013). These meshworks are attached to the inner nuclear membrane through lamina-associated proteins that are either integral or peripheral membrane proteins. The LINC (linker of nucleoskeleton and cytoskeleton)-complex, which traverses the nuclear envelope, further connects the nuclear lamina to the cytoplasmic cytoskeleton. The outer nuclear membrane components of the LINC-complex are nesprins (nuclear envelope spectrin repeat proteins). Specific nesprin isoforms bind directly to actin or indirectly to intermediate filaments via plectin to determine positioning of the nucleus (Wilhelmsen *et al.*, 2005).

Nuclear deformability depends on the level of lamin expression. High lamin levels correspond to stiffer nuclei (Pajeroski *et al.*, 2007). Consequently, lamin A/C-deficient

nuclei are more deformable, more fragile, and prone to spontaneous rupture, and lamin B-deficient cells show increased extrusions of nuclear material into the cytoplasm that are referred to as nuclear blebs (Lammerding *et al.*, 2006).

Lamins and their associated proteins control positioning of chromosomes. Chromatin is bound to lamin through specific DNA sequences, called matrix attachment regions. For example, the *Drosophila melanogaster* lamin Dm0 has been shown to interact with transcriptionally silent DNA sequences that are often localized to the nuclear periphery (Pickersgill *et al.*, 2006). In addition, lamin domains bind to core histones and through several lamin-binding proteins indirectly to chromatin. Further evidence for the involvement of lamins in the regulation of transcription was provided by studies that examined lamin mutants lacking the head domain and revealed inhibition of RNA polymerase II (Spann *et al.*, 2002). Furthermore, lamins A and C were shown to interact with a nuclear zinc finger transcription factor affecting transcription and posttranscriptional processing (Dreuillet *et al.*, 2002).

Lamins and their associated proteins have been shown to regulate the activity and accessibility of signaling molecules (Burke and Stewart, 2013). For example, lamin A is able to interfere with TGFβ signaling via segregation and modification of TGFβ-dependent intracellular mediators (Berlo *et al.*, 2005; Pan *et al.*, 2005).

Intermediate Filament Proteins Are Posttranslationally Modified

Intermediate filament proteins are subject to several types of posttranslational modification resulting in amino acid modification, protein aggregation and rearrangement, and degradation. In this way the intermediate filament system adapts to and reflects different functional states of a given cell (Snider and Omary, 2014).

During mitosis cells need to disrupt their cytoskeleton which is tightly coupled to phosphorylation of intermediate filament proteins. While actin filaments and microtubules are depolymerized and used for specific functions during cell division, intermediate filaments do not participate in essential mitotic processes. But they need to be redistributed to the daughter cells. Some cells disassemble their cytoplasmic intermediate filament network into aggregates (Figure 5) while others only show restricted disassembly at the cleavage furrow. After cell division, fully extended cytoplasmic intermediate filament networks are reestablished. During mitosis an increase in serine and threonine phosphorylation of the head and tail domains occurs, which leads to increased intermediate filament protein solubility and altered intermediate filament network morphology. Phosphorylation-deficient vimentin mutants have been shown to interfere with cytokinesis resulting in binucleated cells (Goto and Inagaki, 2014). Similarly, an increase in phosphorylation of the nuclear lamins occurs during nuclear lamina disassembly in mitosis. Ablation of the phosphorylated serine residues leads to the inhibition of nuclear lamina disassembly (Heald and McKeon, 1990).

In contrast, phosphorylation of neurofilaments has a stabilizing function. Neurofilaments are among the most

Figure 5 Intermediate filament network organization in a cultured cell in interphase and at the onset of mitosis. The fluorescence micrograph in (a) was taken from an interphase cell producing fluorescent protein-tagged keratin intermediate filament proteins. Note the dense network extending throughout the cytoplasm with smaller particles in the periphery. The time series in (b–b'') shows part of a similar cell entering mitosis. Within a few minutes the filament network is broken down into multiple small granules. Images were kindly provided by Marcin Moch (a) and Dr. Stefan Wöll (b–b'').

abundant and most highly phosphorylated proteins in neurons and form tightly clustered bundles providing mechanical support for axonal processes. Furthermore, phosphorylation of neurofilaments is linked to an increased axonal diameter resulting in increased conduction velocity (Perrot *et al.*, 2008).

Sumoylation, the covalent and reversible attachment of small ubiquitin-related modifier (SUMO) proteins, is a conserved posttranslational modification of intermediate filaments and regulates filament formation and solubility. Inhibition of sumoylation in *Caenorhabditis elegans* resulted in aggregate formation of the intermediate filament protein IFB-1 in the epidermis which was accompanied by reduced intermediate filament turnover and abnormal embryonic elongation (Kaminsky *et al.*, 2009). Furthermore, sumoylation has been shown to be important for the localization of lamin A (Zhang and Sarge, 2008).

O-linked glycosylation, the enzymatic addition of beta-D-N-acetylglucosamine to serine and threonine residues, is related to nutrient sensing and stress responses. In simple epithelia glycosylation of keratin 18 promotes the phosphorylation and activation of cell survival kinases in stress situations (Ku *et al.*, 2010).

Intermediate filaments are cleaved by caspases during apoptosis and are ubiquitinated to be subjected to proteasomal degradation during normal cell homeostasis (Snider and Omary, 2014).

A well worked-out example of successive posttranslational modifications is provided by lamins (Burke and Stewart, 2013). They are initially translated as pre-lamins whose cysteine residue in their C-terminal -CAAX motif becomes modified by addition of the 15-carbon isoprenoid farnesyl. Next, the -AAX part is removed. Subsequently, the cysteine residue becomes carboxymethylated generating the mature membrane-anchored B-type lamin. In case of A-type lamins, the C-terminal 15 amino acids including the modified cysteine residue are cleaved off producing mature lamin A, which lacks the farnesyl membrane anchor.

Intermediate Filaments Serve Many Functions

For a long time intermediate filaments were thought to exclusively support the structural integrity of cells. Recent

research efforts, however, uncovered many other functions in cell growth, migration, cellular architecture, and stress-related signaling (Toivola *et al.*, 2005, 2010; Pekny and Lane, 2007; Magin *et al.*, 2007; Kim and Coulombe, 2007).

Intermediate Filaments Provide Structural Support

The identification of intermediate filament mutations in diseases that are characterized by tissue fragility provides compelling evidence for the structural function of intermediate filaments. This is best exemplified in human skin disease, where single point mutations in keratin genes induce blistering in mechanically challenged areas. Furthermore, epithelial cells lacking cytoplasmic intermediate filaments are less resistant to mechanical stress evoked by magnetic tweezers or optical stretching (Ramms *et al.*, 2013; Seltmann *et al.*, 2013). Similarly, fibroblasts without vimentin display decreased stiffness and increased instability when subjected to mechanical challenges (Eckes *et al.*, 1998). Desmin deficiency results in myopathy with impaired force transmission in skeletal and heart muscle (Capetanaki *et al.*, 2007).

Evidence for mechanosensitive functions of intermediate filaments was provided in shear stress experiments of lung epithelial cells, which reacted by increasing keratin solubility, aggregation, and degradation (Ridge *et al.*, 2005). Vimentin expression in blood vessels is increased when high shear stress is applied strengthening the arterial wall structure and counteracting arterial diameter enlargement (Schnittler *et al.*, 1998).

Nuclear shape is at least partly determined by lamins. For example, spermatocytes which have a unique hook-shaped nucleus specifically express lamin B3. Ectopic expression of lamin B3 in somatic cells, which usually have a spherical nucleus, induced hook-shaped nuclei (Furukawa and Hotta, 1993). Lamin mutations furthermore result in elongated skeletal and myocardial nuclei and increased susceptibility to nuclear fragility (Burke and Stewart, 2013).

Intermediate Filaments Support Specialized Tissue Functions

In order to maintain the structure and barrier function of the epidermis, keratinocytes need to differentiate from proliferating cells in the basal layer toward postmitotic, tightly sealed cells in the upper cell layer which eventually die by apoptosis

and give rise to the stratum corneum that is made up by the cornified envelope and aggregated keratins. These differences in cellular differentiation are reflected by different keratin pairs with keratins 5 and 14 in the basal cell layer and increasing levels of keratins 1 and 10 in the suprabasal cell layers. Injury induces the expression of keratins 6 and 16 to support wound closure. Disruption of keratin genes therefore results in reduced mechanical stability, altered wound closure and compromised barrier function in the epidermis (Homberg and Magin, 2014).

Keratins have been linked to secretion in endocrine cells of the pancreas. Reduced insulin levels were observed in mice lacking keratin 8 (Alam *et al.*, 2013). In colonic mucosa, keratins are important for proper electrolyte transport (Toivola *et al.*, 2005).

During axonal growth, neurofilament subunits are incorporated throughout the axon in a dynamic process that involves the addition of subunits along the entire filament length as well as at filament ends. The amount and specific admixtures of neurofilaments along with their phosphorylation state determine axonal diameter and are therefore responsible for diameter-dependent axonal conduction velocity (Liem and Messing, 2009).

Intermediate Filaments Are Guardians of Cells in Stressful Situations

In stress situations intermediate filaments are usually hyperphosphorylated resulting in changed network morphology and intermediate filament protein solubility (Ridge *et al.*, 2005; Snider and Omary, 2014). Interestingly, heat shock proteins, which are increased during heat stress, bind some intermediate filaments (Toivola *et al.*, 2010).

Intermediate filament proteins protect cells from apoptosis. Their hyperphosphorylation acts as a phosphate sink preventing the phosphorylation and therefore activation of proapoptotic factors (Lai *et al.*, 1993; Ku and Omary, 2006). Consequently, keratin-deficient mice are generally more susceptible to apoptosis induced by toxins or other stressors.

Nestin, an intermediate filament protein that is usually expressed during development and downregulated in the adult organism, is reexpressed during pathological situations such as glial scar formation in the central nervous system and regeneration of injured muscle tissue. Relevant in this context may be the interaction of nestin and Cdk5 to promote cell survival (Sahlgren *et al.*, 2006).

Intermediate Filaments Are Reorganized During Migration, Wound Healing, and Tissue Remodeling

Cell migration and wound healing strongly depend on the fundamental reorganization of the intermediate filament cytoskeleton (DePianto and Coulombe, 2004; Ivaska *et al.*, 2007; Chung *et al.*, 2013). Thus, induction of usually absent keratin isoforms is observed during wound healing in epidermal keratinocytes to make them more malleable for repopulating the wounded area. Similarly, there is a rapid upregulation of vimentin and nestin during repair of damaged muscle. Peripheral blood mononuclear cells of mice lacking

vimentin have a reduced capacity to home to lymph nodes and spleen because surface receptors involved in homing are aberrantly expressed and distributed in both the blood mononuclear cells and endothelial cells. This indicates an important role of intermediate filaments in anchoring and organizing adhesion molecules.

In the brain, tissue reorganization following insults is also coupled to altered intermediate filament expression. Peripherin is induced in cerebral ischemia and GFAP is upregulated in glial scar formation.

Intermediate Filaments Contribute to Organelle Localization

Intermediate filaments are involved in the positioning, shaping, and function of cellular organelles (Styers *et al.*, 2005; Toivola *et al.*, 2005). Mitochondria in cardiac muscle of desmin knock-out mice are therefore mislocalized, fragmented, and functionally altered. Mitochondria are also aberrantly distributed in skin diseases caused by mutations in keratin genes. Disease-associated mutations of neurofilament proteins cause fragmentation of the Golgi apparatus.

Vimentin, peripherin, and alpha-internexin bind to an adaptor protein that carries vesicles between endosomal and lysosomal compartments and regulates sorting of different vesicles. In vimentin-null cells the uniform localization of lysosomes throughout the cytoplasm is lost and lysosomes are concentrated near the nucleus.

Cytoplasmic Intermediate Filament Dysfunctions Cause Tissue-Specific Diseases

Hereditary skin diseases and degenerative diseases of muscles and neurons are characterized by disruption of the intermediate filament network and prominent intermediate filament protein-containing cytoplasmic aggregates (Liem and Messing, 2009; Coulombe *et al.*, 2009; Clemen *et al.*, 2013). The highly conserved helix initiation and termination motifs of the central rod domain contain genetic hotspots for the most severe disease mutations. These mutations interfere with filament assembly and network stability.

The clinical importance of keratin intermediate filaments became first evident when single point mutations in the epidermal keratin 14 were linked to the skin disease epidermolysis bullosa simplex. A hallmark feature of this disease is the formation of blisters in the basal layer of the epidermis because of cytolysis, i.e., cell rupture. Cytoplasmic keratin aggregates are pathognomonic features in electron micrographs. Subsequently, skin disease-related mutations were identified in all other epidermal keratins. The localization of the respective pathologies reflected in each case the distribution of the affected keratin. In addition to blistering, increased proliferation and altered differentiation were observed to different degrees. Similar phenotypes are reproduced in mice lacking keratins. Surprisingly, multilayered epidermis is still established in the absence of all epidermal keratins. In addition to pronounced blistering, however, considerable deficiencies in epidermal differentiation and barrier formation occur in this situation (Figure 6).

Figure 6 Blister formation in keratin-deficient mouse epidermis. The picture shows a toluidine blue-stained histological section of murine skin lacking keratin filaments. A multilayered epithelial tissue is still formed. But tissue resilience is considerably compromised resulting in blister formation because of cytolysis. bv, blood vessel; ct, connective tissue; ep, epidermis. The tissue sample was kindly provided by Dr. Thomas Magin, Leipzig University.

Mutations of hard keratins have been linked to human diseases affecting hair and nails (Langbein and Schweizer, 2005). In contrast to soft keratins, which possess glycine- and serine-rich head and tail domains, hard keratins possess cysteine- and proline-rich end domains. They form tight cross-links with each other and with keratin-associated proteins. The most common hard keratin-related disease is monilethrix. It is characterized by fragile hair and nail deformities. Affected individuals display periodic changes in the width of the hair shaft leading to beaded hair that easily breaks.

In simple keratins mutations of the helix entry and termination regions have not been identified as direct causes of human disease. But mutations in their head and tail domains predispose to chronic liver disease. This is apparently related to decreased stress protection. In addition, simple keratin-rich aggregates, Mallory bodies, are typical for cirrhotic liver disease (Strnad *et al.*, 2008).

Mutations in vimentin, phakinin, and filensin have been identified in human cataract patients (Song *et al.*, 2009). Similarly, deletion of filensin or phakinin or expression of mutant vimentin leads to opacification and cataract formation in mice.

Desmin mutations are associated with progressive skeletal myopathy that leads to skeletal muscle weakness in combination with cardiac arrhythmia and heart failure (Clemen *et al.*, 2013). A distinctive histopathological feature is

the accumulation of amorphous cytoplasmic deposits containing desmin and other proteins.

Mutations in the GFAP gene cause Alexander disease, a rare degenerative disease of the white matter in the brain which leads to loss of myelin (Liem and Messing, 2009). Again, cytoplasmic protein aggregates occur that contain several ubiquitinated stress proteins along with the mutant GFAP. Mutations of neurofilament proteins have been identified in neurodegenerative Charcot-Marie-Tooth disease. Affected individuals progressively lose muscle tissue and touch sensation.

Lamin Intermediate Filament Mutations Cause Complex Syndromes

Progeria infantilis or Hutchinson-Gilford syndrome is one of the most remarkable laminopathies (Worman and Bonne, 2007). It leads to premature aging and cardiac dysfunction. The rare disease has been linked to mutations in the lamin A gene, which cannot be processed into the mature form by cleavage of the farnesylated and methylated carboxy-terminus. Restructuring of the nuclear lamina is observed in several cell types. It is characterized by dissociation of heterochromatin from the nuclear periphery and by changes in histone methylation. The lamin A mutations also induce increased nuclear stiffness. In contrast, laminopathies, which are caused by other lamin A mutations and lamin B mutations and lead to muscle dystrophy syndromes, are associated with reduced nuclear stiffness and increased nuclear envelope fragility.

Highly Diverse Intermediate Filament Proteins Occur Throughout the Animal Kingdom

A prominent feature of intermediate filament proteins is their high degree of sequence diversity. Evolutionary pressure is apparently placed on the basic design of the rod domain but neither on its specific amino acid composition nor on the sequences in the highly variable end domains. This diversity enables intermediate filaments to perform isotype-specific functions in different cellular environments. It may explain why large intermediate filament multigene families have evolved and why the individual family members are still rapidly evolving. For example, silencing of a hair keratin gene in humans occurred as recently as 200 000–240 000 years ago (Winter *et al.*, 2001).

Although intermediate filaments are apparently absent in plants and fungi, they are present throughout the animal kingdom (Erber *et al.*, 1998; Peter and Stick, 2012). Comparing intron positions of intermediate filament genes and the amino acid sequences of their encoded polypeptides indicates that they evolved from a lamin-like ancestor. Simple metazoans such as *Hydra attenuata* express only nuclear intermediate filaments. In the invertebrate nematode *C. elegans*, however, 1 nuclear and 11 cytoplasmic intermediate filament genes have been identified. The cytoplasmic intermediate filament proteins contain an elongated coil 1B domain as is typical for lamins. They can be subdivided into two expression groups: Group 1 involves IFB-1 co-assembled with IFA variants in a cell-specific manner; group 2 consists of the 6 remaining intermediate filament proteins that are co-expressed in the

intestine. The nuclear intermediate filament encoded by the single *lmn-1* gene is expressed in all nuclei and localizes to the nuclear envelope. The insect *D. melanogaster* has two nuclear lamin-type intermediate filament proteins but lacks cytoplasmic intermediate filaments. The recent identification of the cytoplasmic intermediate filament-like protein isomin in the intestine of the basal hexapod *Isotomurus maculatus* provides an evolutionary link between the different metazoan phyla (Mencarelli *et al.*, 2011).

Septins: Cytoskeletal Filaments with Structural and Regulatory Functions

ET Spiliotis and L Dolat, Drexel University, Philadelphia, PA, USA

© 2016 Elsevier Inc. All rights reserved.

Similar to microtubules, actin microfilaments and intermediate filaments, septins constitute a network of filamentous polymers, which are essential for the development and physiological functions of eukaryotic organisms. Septin filaments associate with cell membranes and the actin and microtubule cytoskeleton, exhibiting a structural and functional interdependence that distinguishes them apart from the conventional cytoskeleton. Septin filaments function as diffusion barriers and scaffolds that affect the compartmentalization of cell membranes and the spatial organization and functions of the microtubules and actin cytoskeleton (Caudron and Barral, 2009; Spiliotis and Gladfelter, 2012).

Septins are guanosine-5'-triphosphate (GTP)-binding proteins that self assemble into nonpolar oligomers and polymers (Weirich *et al.*, 2008; Mostowy and Cossart, 2012). Like actin and microtubules, septin assembly is coupled to nucleotide-binding and hydrolysis (Gasper *et al.*, 2009). Resembling the hetero-polymeric nature of intermediate filaments, septin filaments consist of various subunits, which in mammalian organisms are encoded by 13–14 different genes with alternative splicing and translation initiation sites that give rise to multiple septin isoforms (Russell and Hall, 2011).

Septin Structure, Assembly, and Dynamics

Classified under the P-loop superfamily of nucleotide-binding and hydrolyzing proteins, which includes the Ras-like GTPases and the kinesin and myosin motors, septins possess a highly conserved GTP-binding domain (G domain), which is structurally characterized by α -helices and β -sheets that alternate between flexible loops (Leipe *et al.*, 2002). Septin G domains contain the G1 Walker A (GxxxGKS/T), G3 Walker B (DxxG), and G4 (NKxD) motifs, which interact directly with atoms of the guanine nucleotide. In addition to these signature motifs,

the N- and C-termini of the septin G domains are respectively characterized by a polybasic region, which binds phosphoinositides (Zhang *et al.*, 1999; Casamayor and Snyder, 2003), and a conserved sequence of unknown function termed the septin unique element (SUE) (Versele and Thorner, 2005). Beyond these homology domains, septins differ significantly in the length and sequence of their N- and C-terminal extensions, which flank their G domains and consist of proline-rich and α -helical domains, respectively (Pan *et al.*, 2007).

Based on amino acid similarity, mammalian septin paralogs are categorized into four groups: SEPT2, SEPT6, SEPT7 and SEPT9 (Pan *et al.*, 2007). The majority of septins fall under the SEPT2 group, which includes SEPT1, SEPT2, SEPT4, and SEPT5, and the SEPT6 group, which consists of SEPT6, SEPT8, SEPT10, SEPT11, and SEPT14 (Figure 1). Lacking a critical threonine residue from their G domains, septins of the SEPT6 group are posited to be hydrolytically inactive and always bound to GTP (Sirajuddin *et al.*, 2009; Zent and Wittinghofer, 2014). The remaining septins are classified under the SEPT9 group, which comprises SEPT3, SEPT9, and SEPT12, and the SEPT7 group, which contains SEPT7 isoforms (Figure 1). SEPT2, SEPT7, and SEPT9 are nearly ubiquitously expressed, while SEPT1, SEPT3, SEPT12, and SEPT14 are tissue-specific (Dolat *et al.*, 2014a). The remaining septins are expressed widely, but not present in every tissue (Dolat *et al.*, 2014a).

Septin polymerization is driven by the propensity of their G domains to homo- and hetero-dimerize (Sirajuddin *et al.*, 2007). In the presence of guanosine nucleotide, septin G domains dimerize by interacting directly through their GTP-binding pockets (G interface), which are oriented opposite to one another, or, alternatively, through their N- and C-terminal helices (NC interface). Using the G and NC dimerization interfaces in tandem, septin monomers assemble linearly into nonpolar oligomers (Sirajuddin *et al.*, 2007). In mammalian systems, the basic septin oligomer is a hetero-octamer

Figure 1 Septin filament assembly. Mammalian septins are classified in four groups (SEPT2, SEPT6, SEPT7, and SEPT9) and characterized by highly conserved domains such as a phosphoinositide-binding polybasic domain (PD), a GTP-binding domain, a septin unique element (SUE) and C-terminal α -helical coiled coil (CC) domains. Septins form nonpolar hetero-oligomeric complexes by dimerizing in tandem using their GTP-binding domains, which interact with one another via their N- and C-terminal helices (NC interface) or their GTP-binding pockets (G interface). GTP hydrolysis favors oligomerization by stabilizing the G interface, but septins of the SEPT6 group do not hydrolyze GTP. End-to-end assembly of septin hetero-oligomers results in the formation of nonpolar filaments, which interact laterally through the N- and C-terminal extensions of their septin subunits. Owing to the flexibility of the NC interface, paired septin filaments can bend into curved and ring-like bundles. In addition to septin bundles and rings, membrane-associated septins form gauze-like structures, which consist of orthogonally arranged filaments. Septin filaments and structures are not drawn to scale.

composed of septins from each of the SEPT2, SEPT6, SEPT7, and SEPT9 groups at a 2:2:2:2 stoichiometry (SEPT9-SEPT7-SEPT6-SEPT2-SEPT2-SEPT6-SEPT7-SEPT9) (Kim *et al.*, 2011; Sellin *et al.*, 2011b). This mode of hetero-octameric assembly is conserved between mammals and yeast (Bertin *et al.*, 2008; Farkasovsky *et al.*, 2005), but septin filaments could also consist of hetero-hexameric (SEPT7-SEPT6-SEPT2-SEPT2-SEPT6-SEPT7) and – tetrameric (SEPT6-SEPT7-SEPT7-SEPT6) units (Kinoshita, 2003; Sellin *et al.*, 2014). In addition, ‘non-canonical’ hetero-oligomers that consist of multiple subunits of the same septin group may also exist (Dolat *et al.*, 2014a). Overall, septin hetero-oligomers could vary in size and composition depending on cell and tissue type. Irrespective of subunit identity, presence of guanosine-5'-diphosphate (GDP) and thus GTP hydrolysis favors oligomerization by stabilizing the G interface, while GTP-binding appears to destabilize the NC interface (Zent and Wittinghofer, 2014). With the exception of SEPT6, oligomeric septins are GDP-bound and septin polymers contain an excess of GDP relative to GTP (Sirajuddin *et al.*, 2007; Farkasovsky *et al.*, 2005). Therefore, in contrast to microtubules and actin microfilaments whose polymerization is favored by a non-hydrolyzed nucleotide, septin polymerization is favored by GTP hydrolysis (Table 1).

Septin hetero-octamers polymerize into higher order structures such as linear and curved filaments, rings and gauze-like meshworks (Kinoshita *et al.*, 2002; Bertin *et al.*, 2008; Garcia *et al.*, 2011). End-to-end binding of septin hetero-octomers results in filaments, which are 5–10 nm wide and up to several microns long (Kinoshita *et al.*, 2002; Bertin *et al.*, 2008, 2010). Septin filaments pair with one another by interacting laterally through the C- (coiled coil domains) and possibly N-terminal extensions that stretch outwards from the plane of oligomerization (Bai *et al.*, 2013; John *et al.*, 2007; Bertin *et al.*, 2008; de Almeida Marques *et al.*, 2012). Thus, septin bundles form by lateral stacking of individual septin filaments and adapter proteins further enhance septin bundling (Sadian *et al.*, 2013). Owing to the flexibility of the SEPT2 NC interface, which behaves like a hinge, septin oligomers can bend within a 25–30° angle of one another generating a curvature, which allows for the formation ring-like structures with 0.5–0.7 µm diameter (Sirajuddin *et al.*, 2007). Septin subunits that enhance the flexibility of NC interface favor the formation of septin rings and posttranslational modifications can promote the assembly of a gauze-like meshwork of orthogonally arranged filaments (Garcia *et al.*, 2011). The

filamentous pattern of septins is further influenced by their association with membrane bilayers and the actin and microtubule cytoskeleton. Membranes enriched with phosphatidylinositol-4,5-bisphosphate promote the formation of tightly paired septin filaments (Bertin *et al.*, 2010; Tanaka-Takiguchi *et al.*, 2009). Conversely, actin-templated assembly of septins favors the formation of linear filaments as opposed to septin rings, which become more prevalent upon actin depolymerization (Kinoshita *et al.*, 2002; Schmidt and Nichols, 2004b). Similarly, the disk-like organization of septins in non-adherent cells depends on microtubules (Sellin *et al.*, 2011a; Martinez *et al.*, 2006).

Septin filaments are less dynamic than microtubules and F-actin. Half-times of subunit exchange and turnover could vary from 10 s of seconds for cytoplasmic septin filaments in mammalian cells to 3 min for membrane-associated septin polymers in yeast organisms (Schmidt and Nichols, 2004b; Hagiwara *et al.*, 2011; Hu *et al.*, 2008; Dobbelaere *et al.*, 2003; DeMay *et al.*, 2010). Recent studies show that membrane-bound septin filaments grow by end-to-end annealing (Bridges *et al.*, 2014). Rod-shaped septin oligomers diffuse, collide and anneal to the free ends of septin filaments, which do not exchange any subunits along their length (Bridges *et al.*, 2014). In contrast to membrane-bound septin filaments, which incorporate new subunits after fragmentation, cytoplasmic septin filaments are more dynamic, exchanging subunits along their length (Schmidt and Nichols, 2004b; Hu *et al.*, 2008; Bridges *et al.*, 2014). Septin filament dynamics are affected by posttranslational modifications such as phosphorylation and acetylation, and vary depending on the phase of the cell cycle (Hernandez-Rodriguez and Momany, 2012). For example, in the budding yeast *Saccharomyces cerevisiae*, septin filaments are dynamic in G1, but highly stable during the S, G2 and M phases of the cell cycle (Dobbelaere *et al.*, 2003). These changes in septin dynamics are mediated by septin-dependent kinases and phosphatases that are recruited to septin filaments in the beginning and end of the cell cycle, respectively (Dobbelaere *et al.*, 2003).

The molecular mechanisms that regulate septin assembly and dynamics are not fully understood. Recent advances indicate that regulation of GTP hydrolysis, septin synthesis and degradation as well as posttranslational modifications and protein–protein interactions influence the filamentous organization and dynamics of septins. Septin folding is mediated by the cytosolic chaperonin-containing TCP-1 (CCT), which also

Table 1 Septins in comparison to actin microfilaments, microtubules and intermediate filaments

	<i>Septins</i>	<i>F-actin</i>	<i>Microtubules</i>	<i>Intermediate filaments</i>
Subunit(s)	SEPT1-14	α -/ β -/ γ -actin	α -/ β -tubulin	Keratin, vimentin, lamin, desmin, peripherin, nestin, and neurofilament proteins
Nucleotide	GTP	ATP	GTP	None
Diameter	~5 nm	~7 nm	~25 nm	~10 nm
Length	25–32 nm to several microns	Several microns	Several microns	Several microns
Structure	Straight or curved paired filaments, rings and gauzes	Right-handed helix	Hollow tube	Twisted filaments
Polarity	No	Yes	Yes	No
Subunit turnover ($t_{1/2}$)	10–200 s	10 s of seconds	10 s of seconds	10 s of minutes

controls the folding of actin and tubulin, and septin degradation involves E3 ubiquitin ligases including parkin, the von Hippel-Lindau (VHL) tumor suppressor and the Ring Finger protein 8 (RNF8) (Craven *et al.*, 2006; Chahwan *et al.*, 2013; Dekker *et al.*, 2008; Zhang *et al.*, 2000). While these factors could regulate the availability of septin subunits for polymerization, proteins that promote the GTPase activity of septins (e.g., Orc6) and crosslink septin filaments (e.g., Gic1) can directly enhance septin assembly (Sadian *et al.*, 2013; Huijbregts *et al.*, 2009). In contrast, Cdc42, a signaling molecule of the Rho family of GTPases, induces the unbundling and dissociation of septin filaments (Sadian *et al.*, 2013). Post-translational modifications such as phosphorylation, acetylation and sumoylation further modulate septin assembly and dynamics, but many of the details remain unknown (Hernandez-Rodriguez and Momany, 2012).

Septins and the Membrane Skeleton

Septin filaments assemble on the cytoplasmic leaflet of membrane bilayers forming a meshwork that resembles the spectrin-actin membrane skeleton. In yeast cells, septins form filamentous rings and gauze-like patches in actin-free areas of the cell cortex (Oh and Bi, 2011; McMurray and Thorner, 2009), while in mammalian cells septin filaments associate with the actin membrane skeleton (Hagiwara *et al.*, 2011). These membrane-bound septin filaments restrict protein diffusion and affect the shape and rigidity of cell membranes (Spiliotis and Gladfelter, 2012; Caudron and Barral, 2009).

In the budding yeast *S. cerevisiae*, a membrane-bound septin ring forms at the base of the emerging bud early in the cell cycle and evolves to a collar that underlies the mother-bud neck (McMurray and Thorner, 2009; Oh and Bi, 2011). Septin filaments are positioned between the plasma membrane and the smooth endoplasmic reticulum (ER), impeding the lateral diffusion of cortical and ER membrane proteins during polarized bud growth (Barral *et al.*, 2000; Luedeke *et al.*, 2005). In mitosis, splitting of the septin collar into two rings results in the formation of a membrane compartment, which enables the accumulation of membrane-associated factors (e.g., vesicle tethering complexes) without diffusing into the mother and bud cell membranes (Dobbelaere and Barral, 2004). During mammalian mitosis, a septin diffusion barrier is posited to similarly limit the diffusion of inner leaflet membrane proteins across the equatorial plane of a dividing cell (Schmidt and Nichols, 2004a).

Septins form membrane-bound rings at the base of the primary cilium and the dendritic spines of neurons (Hu *et al.*, 2010; Tada *et al.*, 2007; Xie *et al.*, 2007). At the interface of the plasma and ciliary membrane, septins control the localization of ciliary membrane proteins and thus, they are required for the formation and maintenance of the primary cilium (Hu *et al.*, 2010). Septins could similarly impede the lateral diffusion of post-synaptic proteins from the dendritic spines to the shaft, aiding to the compartmentalization of synaptic receptors and channels (Caudron and Barral, 2009). At the annulus of spermatozoa, septins form a barrier between the principal and mid pieces of the sperm, and are required for the proper localization of a protein that is essential for

spermiogenesis (Kwitny *et al.*, 2010). The mechanism by which septins restrict lateral diffusion in cell membranes is unknown, but recent evidence indicates that septins influence the organization of lipid domains and interact with the cytoplasmic tails of membrane transporters (Sharma *et al.*, 2013; Hagiwara *et al.*, 2011). Protein-lipid compartmentalization and domain identity could be further reinforced by septin-mediated inhibition of vesicle delivery; septins interact with the exocyst, a vesicle tethering complex, and components of the soluble N-ethylmaleimide-sensitive factor activating protein receptor (SNARE) machinery of vesicle fusion, and may introduce a physical barrier that interferes with vesicle delivery to the plasma membrane (Beites *et al.*, 1999; Hsu *et al.*, 1998; Yang *et al.*, 2010). Hence, septins are an integral component of the structure of cell membranes, contributing to the organization of membrane domains by inhibiting selectively the lateral diffusion and delivery of membrane proteins.

In addition to their diffusion barrier properties, membrane-bound septins affect the shape and physical properties of lipid bilayers. Similar to the membrane-remodeling functions of the Bin-Amphiphysin-Rvs (BAR)-domain proteins, septins have been shown to induce the tubulation of spherical liposomes made of phosphatidylcholine and phosphoinositides (Tanaka-Takiguchi *et al.*, 2009). These membrane tubules have the diameter of septins rings ($\sim 0.5 \mu\text{m}$) and are circumferentially braced by septin filaments (Tanaka-Takiguchi *et al.*, 2009). It is unknown, however, whether septins affect membrane curvature and induce membrane tubules *in vivo*. Conversely, several studies have shown that septin depletion decreases the rigidity and stiffness of cell membranes (Tooley *et al.*, 2009; Mostowy *et al.*, 2011). In T lymphocytes, septins suppress membrane blebbing and protrusive activity is spatially restricted to septin-free areas of the cell cortex (Tooley *et al.*, 2009; Gilden *et al.*, 2012). Measurements of membrane elasticity and viscosity show a marked decrease in the rigidity of cell membranes after septin depletion, which alters cell shape and morphology (Mostowy *et al.*, 2011). Thus, like the spectrin-actin membrane skeleton, septin filaments contribute to the organization and mechanochemical properties of cell membranes.

Septins and the Actin Cytoskeleton

From yeast to mammals, septins are implicated in the organization and functions of the actomyosin cytoskeleton. Septins crosslink actin filaments and interact with actin-binding proteins and signaling effectors that regulate the organization of the actin cytoskeleton (Mavrakakis *et al.*, 2014; Nagata and Inagaki, 2005; Kinoshita *et al.*, 2002). Notably, septins interact directly with myosin II, regulating its localization and activation in interphase and mitotic cells (Joo *et al.*, 2007).

In the budding yeast *S. cerevisiae*, septins are essential for the recruitment of proteins involved in actin cable assembly during bud growth. At the site of bud formation, linear actin cables, which enable the polarized transport of vesicles, are polymerized by the formins Bni1 and Bnr1 (Bretscher, 2013). In the absence of the nonessential septin Shs1, Bnr1 is mis-localized and actin cables fail to assemble (Gao *et al.*, 2010; Buttery *et al.*, 2012). The actin assembly activity of Bnr1 appears to depend on Shs1 (Buttery *et al.*, 2012) and the septin-

interacting partner Bni5 is required for the recruitment of myosin II, which drives actin cable retrograde flow (Nam *et al.*, 2007). Thus, septins scaffold and may activate the assembly of actin cables during bud growth. Interestingly, mammalian

septins scaffold the recruitment of cortactin, an activator of Arp2/3, to actin patches in the axons of sensory neurons (Hu *et al.*, 2012). Septin 6 (SEPT6) localizes to actin patches, which consist of branched actin filaments, and SEPT6 depletion

reduces the recruitment of cortactin to actin patches and their transition to filopodia (Hu *et al.*, 2012). Reconstitution of branched actin assembly *in vitro* and in the presence of Arp2/3 shows that SEPT6 localizes preferentially to actin branch points (Hu *et al.*, 2012). In agreement with this observation, overexpression of SEPT6 increases the recruitment of cortactin to the lamellipodium, a branched actin network at the leading edge of motile cells (Hu *et al.*, 2012). Additional septins (e.g., SEPT1 and SEPT4) are enriched in the lamellipodia of squamous carcinoma cells (Mizutani *et al.*, 2013). Septins, therefore, have an evolutionarily conserved role in scaffolding proteins involved in the formation of linear and branched actin filaments.

More recently, septins were found to crosslink and bundle actin filaments directly, contributing to the assembly of contractile actin rings in *Drosophila* embryos (Mavrakakis *et al.*, 2014). In developing *Drosophila* embryos, the blastoderm contains thousands of nuclei, which become individual cells. Cellularization requires the assembly of contractile rings of actomyosin filaments that furrow the plasma membrane resulting in membrane canals that envelope the nuclei of the syncytial embryo. Embryos expressing a septin mutant are characterized by a loss of circular actin filaments, which are less bundled and contract at slower rates (Mavrakakis *et al.*, 2014). *Drosophila* septins bundle actin filaments and copolymerization of actin with septins results in curved and circular actin bundles (Mavrakakis *et al.*, 2014). Mammalian septins also bundle actin filaments *in vitro* and septin depletion results in loss of actin stress fibers (Schmidt and Nichols, 2004b; Kremer *et al.*, 2007; Dolat *et al.*, 2014b; Kinoshita *et al.*, 2002). These findings indicate that septins are actin-binding and bundling proteins that regulate the organization of actin microfilaments (Figures 2(a)–(g)).

In addition to their direct roles in actin organization, septins influence actin organization and contractility by interacting with signaling factors and myosin II. Assembly of stress fibers is under the control of Rho GTPases, which activate actin nucleation factors and promote the contraction of myosin II (Narumiya *et al.*, 2009). Several studies have indicated that septins are involved in the Rho signaling pathways that control stress fiber assembly. Septin 9 (SEPT9), which is positioned at the terminal ends of septin hetero-octamers, interacts directly with a Rho guanine exchange factor (GEF), termed the septin-

associated Rho GEF (SA-Rho GEF), and Rhotekin, a secondary effector of Rho signaling (Nagata and Inagaki, 2005; Ito *et al.*, 2005). Both SA-Rho GEF and Rhotekin regulate septin assembly and localization to stress fibers. Interestingly, SEPT9 appears to negatively regulate Rho activation by inhibiting GTP loading by the SA-Rho GEF (Nagata and Inagaki, 2005). Septins also interact with Binders of Rho GTPases (Borgs), which are effectors of Cdc42 (Joberty *et al.*, 2001). New studies show that Gic1, a yeast homolog of the human Borg, binds and cross-links septin filaments *in vitro* in a Cdc42-dependent manner (Sadian *et al.*, 2013). Binding of the active Cdc42-GTP to Gic1 results in the dissociation of Gic1 from septin filaments. The inactive Cdc42-GDP, however, also inhibits the assembly of septin filaments by competing with Gic1 for binding to septins (Sadian *et al.*, 2013). In mammalian cells, Borgs have been shown to affect both septin and stress fiber assembly (Joberty *et al.*, 2001).

While more work is needed to elucidate how the interactions between septins and signaling molecules affect actin organization, structural and functional analysis of the septin-myosin II interaction has provided a novel mechanism for the activation of the non-muscle myosin II. The mammalian SEPT2 has been shown to interact directly with the heavy chain of the non-muscle myosin II and yeast two-hybrid data indicate that Myo1, the *S. cerevisiae* type II myosin, binds the sporulation-specific septin Spr3 (Joo *et al.*, 2007; Drees *et al.*, 2001). Disruption of the SEPT2-myosin II interaction results in loss of stress fibers in interphase cells and incomplete ingression of the cleavage furrow during mitosis (Joo *et al.*, 2007). These defects are accompanied by significant reduction in the phosphorylation of the myosin light chain, which stimulates myosin II contractility. Importantly, SEPT2 appears to scaffold the interaction of myosin II with the citron and Rho-activated myosin kinases, which in the absence of septins dissociate from the cleavage furrow (Joo *et al.*, 2007). Thus, septins may control spatially and temporally the localization and activation of myosin II. Importantly, this function might be evolutionarily conserved as myosin activation and actin organization is also disrupted in *Xenopus* embryos after Sept7 depletion, decreasing planar tension and protrusive activity during the collective cell migration that drives body axis elongation (convergent extension) (Shindo and Wallingford, 2014).

Figure 2 Septins interact with the actin and microtubule cytoskeleton. (a–e) Fluorescence images show purified recombinant septins tagged with the green fluorescent protein decorating linear (a), branched (b) and circular (c) actin filaments. Prepolymerized rhodamine-actin (3 μ M) decorated with 100 nM SEPT7-GFP (a), or 400 nM SEPT6-GFP in the presence (b) or absence (c) of unlabeled 15 nM Arp 2/3 and 100 nM VCA (Reproduced from Hu, J., Bai, X., Bowen, J.R., *et al.* 2012. Septin-driven coordination of actin and microtubule remodeling regulates the collateral branching of axons. *Current Biology* 22, 1109–1115.). Recent evidence indicates that septins crosslink actin filaments into curved and circular bundles (Mavrakakis *et al.*, 2014) and scaffold the recruitment of cortactin, an actin nucleation promoting factor, at Arp2/3-mediated branch points (Hu *et al.*, 2012). In the budding yeast *Saccharomyces cerevisiae*, septins are required for the localization and activity of formins, which stimulate the formation of actin cables (d). In the axons of sensory neurons, septins accumulate to actin patches (e), which consist of Arp2/3-nucleated branched filaments, and in *Drosophila* embryos, septins are essential for the assembly of the contractile rings of actomyosin (f), which drives membrane invagination and furrow ingression during cellularization. Scale bars, 1 μ m. (g–l) Fluorescent images show colocalization of septin filaments with actin stress fibers in Cos7 cells (g) and microtubules in Madin-Darby canine kidney cells (h), and *in vitro* decoration of 10 μ m prepolymerized rhodamine-microtubules with 20 nM purified recombinant SEPT7-GFP (Reproduced from Bai, X., Bowen, J.R., Knox, T.K., *et al.*, 2013. Novel septin 9 repeat motifs altered in neuralgic amyotrophy bind and bundle microtubules. *Journal of Cell Biology* 203, 895–905.). (i). Septins bundle microtubules and inhibit their interaction with other microtubule-associated proteins (j). Posttranslational modifications (PTM) of tubulin such as acetylation and polyglutamylation are influenced by septins, which can scaffold the interaction of tubulin with the deacetylase HDAC6 (k). In addition, septins have been shown to guide spatially microtubule-microtubule interactions and may influence the localization of microtubule motors (l). Scale bars, 10 μ m.

In summary, septins are integral components of the actomyosin cytoskeleton. Recent studies have revealed that septins interact directly with actin filaments and myosin II, but many of the molecular and functional details remain unknown. Future studies will address the mechanisms by which septins affect the formation of linear and branched actin filaments and myosin II-dependent contractility, and how septins interface with signaling pathways that affect actin organization and contractility.

Septins and the Microtubule Cytoskeleton

Septin filaments colocalize with microtubules in a diversity of eukaryotic organisms and cells. The extent of septin-microtubule colocalization varies between septin paralogs and isoforms, and depends on cell type, phase of the cell cycle and tubulin isoform expression and posttranslational modifications. Recent studies have shown that septins interact directly with microtubules, microtubule-associated proteins (MAPs) and motors as well as enzymes that modify tubulin's posttranslational modification. Thus, septins have emerged as novel regulators of microtubule organization and dynamics, and may play a key role in the spatial regulation of microtubule-dependent transport (**Figures 2(h)-(l)**).

Mammalian SEPT2/6/7/9 complexes interact directly with microtubules through their SEPT9, SEPT7, and SEPT6 subunits; SEPT2 does not bind microtubules (**Bai et al., 2013**). It is unknown how SEPT6 and SEPT7 associate with microtubules, but SEPT9 interacts with the acidic tails of β II-tubulin via its N-terminal extension, which contains multiple repeats of the K/R-R/x-x-D/E motif (**Bai et al., 2013**). Similar to the microtubule-binding sequence repeats of filamentous MAPs (e.g., tau, MAP1A), the SEPT9 repeat motifs consist of positively and negatively charged residues, which interact electrostatically with one another and the acidic C-terminal tails of β -tubulin (**Bai et al., 2013**). Thus, the N-termini of SEPT9 mediate septin-septin and septin-microtubule interactions that crosslink microtubules into bundles. By forming filamentous cross-bridges that bind microtubules in a staggered arrangement, septins could increase the thickness and length of microtubule bundles as observed *in vitro* (**Bai et al., 2013**). Consistent with this function, septins colocalize preferentially with elongated microtubule bundles in cultured kidney epithelia (**Bowen et al., 2011**). Moreover, expression of SEPT9 isoforms that lack N-terminal repeat motifs reduces both microtubule bundling and septin-microtubule colocalization (**Bai et al., 2013**). Hence, through the properties of SEPT9, mammalian septins function as *bona fide* MAPs that facilitate the bundling of microtubules.

Like most MAPs, septins affect not only microtubule bundling, but also microtubule dynamics. In kidney epithelia, SEPT2 knock-down increases microtubule catastrophe and reduces the rate of microtubule growth, indicating that septins are required for persistent microtubule growth (**Bowen et al., 2011**). Interestingly, loss of SEPT2 also affects microtubule-microtubule interactions and the overall directionality of microtubule growth (**Bowen et al., 2011**). In agreement with a septin requirement for microtubule growth and bundling, SEPT9 knock-down decreased the density of the microtubule

network in mammary epithelia (**Bai et al., 2013**). Depletion of SEPT7, however, has the opposite effect in HeLa cells, increasing microtubule density and acetylation, a marker of microtubule stability (**Kremer et al., 2005**). A direct interaction between SEPT2 and MAP4 indicates that cytoplasmic SEPT2/6/7 complexes inhibit MAP4 from binding and bundling microtubules, but SEPT2/6/7 and MAP4 also compete for binding to microtubules and a new study shows that SEPT7 mediates the interaction of α -tubulin with the deacetylase histone deacetylase 6 (HDAC6) (**Spiliotis et al., 2008**; **Ageta-Ishihara et al., 2013**). Surprisingly, SEPT7 is required for α -tubulin deacetylation and SEPT7-depleted neurons have increased levels of acetylated tubulin and reduced rates of microtubule growth (**Ageta-Ishihara et al., 2013**). While the cause-and-effect relationship between microtubule 'stability' and acetylation is unclear, septins appear to affect microtubule bundling, dynamics, and posttranslational modifications including acetylation and polyglutamylation. Given that septins interact with β -tubulin, MAP4 and HDAC6 in a paralog- and isoform-specific manner, it is possible that septins have distinctly different roles, targeting different aspects of microtubule organization and dynamics.

Microtubule posttranslational modifications and MAPs affect the binding and processive movement of motors, generating a code for the spatial regulation of intracellular transport (**Verhey and Gaertig, 2007**). Presence of septins on select microtubule tracks (e.g., perinuclear microtubule bundles) raises the possibility that septins regulate microtubule-dependent transport (**Spiliotis et al., 2008**). In kidney epithelial cells, tubular vesicular carriers egress from the trans-Golgi network on septin-coated microtubule tracks (**Spiliotis et al., 2008**). Microinjection of septin function-blocking antibodies or SEPT2 depletion results in stalling of vesicle transport *en route* to the plasma membrane (**Spiliotis et al., 2008**). Competition between SEPT2 and MAP4 for binding to microtubules suggests that septins could block the microtubule binding of MAP4, which inhibits kinesin-dependent transport (**Spiliotis et al., 2008**). It is unknown whether septins affect directly the binding or processive movement of microtubule motors, but SEPT7 interacts directly with the mitotic motor centromere associated protein E (CENP-E) (kinesin 7) (**Zhu et al., 2008**). Interestingly, septins are required for the proper localization of CENP-E and consequently, for the stable capture and biorientation of the kinetochores of congressing chromosomes (**Spiliotis et al., 2005**). Because SEPT7 interacts with the C-terminal tail of CENP-E, which binds and inhibits the motor domain of CENP-E, SEPT7 could promote the activation and motility of CENP-E by relieving its auto-inhibition. Alternatively, septins may scaffold the interaction of CENP-E with the Aurora A and B kinases or the protein phosphatase 1 (PP1), which regulate CENP-E binding to microtubules; Aurora B has been reported to interact directly with SEPT1 (**Qi et al., 2005**).

For many years now, the association of microtubules with septins has been an intriguing and contentious observation. Recent studies show that septins interact directly with microtubules, affecting their organization, dynamics and posttranslational modifications. However, more work is needed to determine if and how septins influence the binding and processivity of microtubule motors and whether septins could be

part of the molecular mechanisms that regulate spatially the transport of intracellular cargo.

Conclusions

Septins comprise a network of filaments that interface with cell membranes and the actin and microtubule cytoskeleton. Septins are integral components of the cell membrane's skeleton impeding lateral diffusion and vesicle delivery, and thereby, affecting the generation and maintenance of distinct membrane compartments and domains. In the cytoplasm, septins act as filamentous actin- and MAPs that regulate the spatial organization and functions of the cytoskeleton. Septins interact directly with actomyosin and actin-binding proteins, affecting the localization, formation, cross-linking, and contractility of actin microfilaments. Septins bundle microtubules and appear to regulate the organization, dynamics, and post-translational modifications of microtubules as well as their interactions with motors and MAPs. Thus, septins fine-tune the spatial organization and functions of the cell, regulating a diversity of cellular processes ranging from cell division and motility to cell death and autophagy.

Abnormalities in septin expression and septin mutations underlie a number of disease states (Dolat *et al.*, 2014a). Male infertility and Hereditary Neuralgic Amyotrophy (HNA), an autosomal dominant neuromuscular disorder, are linked to septin gene mutations (Kuo *et al.*, 2012; Kühlenbaumer *et al.*, 2005). Blood disorders such as the Bernard–Soulier Syndrome and acute myeloid and lymphoblastic leukemias are characterized by septin gene deletions and fusions with the mixed lineage leukemia (MLL) gene (Cerveira *et al.*, 2011; Bartsch *et al.*, 2011). Septins are abnormally expressed in many solid tumors of epithelial origin including breast, ovarian, renal and colorectal carcinomas, and changes in epigenetic marks of septin expression have been utilized as diagnostic biomarkers (Connolly *et al.*, 2011). Alterations in septin expression have also been reported in neurodevelopmental disorders (e.g., Down syndrome and schizophrenia) and septin aggregates have been found in the neurofibrillary tangles and Lewy bodies of patients with neurodegenerative disorders such as Alzheimer's and Parkinson's (Dolat *et al.*, 2014a). Recent studies indicate that septins are also important of host defense against pathogenic bacteria (Mostowy and Cossart, 2011). While more studies are required to elucidate how abnormalities in septin expression contribute to the pathogenesis of human diseases, septins are integral components of the cytoskeleton and its functions. Future studies will enhance our understanding of septins as regulators of the spatial organization of the cell.

Bacterial and Archaeal Cytoskeletons

Introduction

Although it was long assumed that the contents of bacteria moved only by diffusion, the discovery of the bacterial cytoskeleton in the 1990s totally changed this view. Prokaryote cells (bacteria and archaea, which all lack a nucleus enclosed by membrane) are now known to possess a variety of filament-forming proteins used for cell shaping, polarization, and division, as outlined in this article (Figure 1). Many of these filament-forming proteins are clearly related to eukaryotic cytoskeletal filaments such as F-actin, microtubules, and intermediate filaments. The great variation in bacteria and archaea within each protein family reflects their long evolutionary history compared with the time that eukaryotes have been in existence. These proteins occur in both Gram-positive bacteria (such as *Bacillus subtilis*) and Gram-negative bacteria (such as *Escherichia coli*) and also in the three archaeal phyla, Euryarchaeota, Crenarchaeota, and Thaumarchaeota. From comparisons among bacteria, archaea, and eukarya of a variety of genetically encoded components, including cytoskeletal filaments, it seems most likely that archaea emerged from early Gram-positive bacteria, while eukaryotes seem to come from archaeal host cells encompassing endosymbiotic organelles (notably mitochondria and chloroplasts) derived from Gram-negative bacteria.

Many dynamic members of the nucleotide-dependent filamentous proteins work as linear motors, pushing or pulling objects through the cell and are thus known as cytomotive filaments. A confusing variety of these have been found. Some bacteria have acquired additional genes only distantly related to their own typical sequences, apparently through horizontal

gene transfer (HGT). Thus, *Verrucomicrobia* have eukaryotic tubulin-like BtubA/B heterodimers that assemble into narrow 5-protofilament microtubules (Pilhofer and Jensen, 2013), whose function in these bacteria is currently unknown. Other species contain plasmids and large phages that code for cytomotive filaments resembling archaeal proteins.

Accessory proteins that link the prokaryotic filaments to their cargoes or to the cell membrane, or act as catalysts of the cytomotive activity, are gradually being investigated; some appear to work in similar ways to known eukaryotic proteins but, unlike the conserved filaments, seem to result from convergent evolution rather than being directly related. So far, no motor proteins related to kinesin, myosin or dynein have been found, from which it can be assumed that the linear motor activity of the filaments is evolutionarily older than their use as static cytoskeletal tracks for motor proteins, as in the eukaryotic cytoskeletal network.

Cytokinesis

Almost all bacteria and many archaea divide by means of a constricting ring at mid-cell consisting of protofilaments of tubulin-related FtsZ (Figures 1(a) and 2). However, some groups of archaea divide using ESCRT filaments (Figure 3) instead of an FtsZ-ring. On either side of the membrane constriction, the 'divisome complex' exports components to the periplasm, where new cell wall is assembled to partition the daughter cells.

Figure 1 Diverse functions of cytoskeletal elements in bacteria. Bacterial cytoskeletal filaments perform cell division, DNA segregation, cell shape maintenance, and cellular compartment organization. Bacterial tubulin homologs shown: FtsZ performs cytokinesis (a), TubZ executes plasmid segregation (b). Bacterial actin homologs shown: FtsA is needed for cell division (a), ParM executes plasmid segregation (c), MamK organizes magnetosome chains (f), MreB maintains cell shape (d). Intermediate filament-like coiled-coil proteins (e.g., Crescentin and Bactofilins) also regulate cell shape (e).

Figure 2 Bacterial filament structures involved in cell division. (a) FtsZ dimer from crystal structure of *Staphylococcus aureus* (PDB ID 3V08), representing two subunits of a straight protofilament (see f). The monomers are colored to distinguish the GTPase domain (blue), the central helix (yellow), and the activation domain (red). The longitudinal interaction between monomers is conserved throughout the tubulin family. Nucleotide (orange) is hydrolyzed by the activation domain of a new subunit adding to the protofilament during assembly. (b) Fluorescence image of an *Escherichia coli* (JM109) cell expressing FtsZ-GFP. FtsZ polymerizes at mid-cell to form the bright Z-ring shown here (Ma *et al.*, 1996). Copyright (1996) National Academy of Sciences, USA. (c) 3D super-resolution imaging of the Z-ring (FtsZ-Dendra2) in a *Caulobacter crescentus* cell. 2D projections of 3D images: side view and cross-sectional view; brighter segments occur where more filaments overlap. Scale bar 200 nm (Biteen *et al.*, 2012). (d) Section through an electron cryotomogram of a *C. crescentus* cell showing Z-ring. (e) In *E. coli*, the Min system oscillates between the cell poles and restricts the FtsZ-ring assembly to the mid-cell. Shown here is GFP-MinC oscillation in fluorescence images of the same cell at different times, 20 s apart. (f) Models showing how FtsZ-based cell division is aided by FtsA at the mid-cell, and how the Min system prevents Z-ring assembly near the cell poles. The FtsZ protofilament shown here is the same structure as (a); FtsA is from *Thermotoga maritima* (PDB ID 4A2B). The MinCD copolymer model was made by combining *Aquifex aeolicus* MinCD co-crystal structure (PDB ID 4V02) and *E. coli* MinD dimer structure (PDB ID 3Q9L). Top: at the cell poles, MinD dimers (blue) bind to the cell membrane, while MinC subunits (yellow) interact with FtsZ filaments via dimerized C-terminal domains and inhibit Z-ring assembly via N-terminal domains. The 8 nm spacing of MinCD copolymers is well-matched to the 4 nm spacing of FtsZ protofilaments (Ghosal *et al.*, 2010). Bottom: at the mid-cell, the MinCD copolymers are unstable due to a dynamic MinE ring (Zheng *et al.*, 2014), but FtsA bound to membrane via the end of its C-terminal extension (red) recruits FtsZ protofilaments which can bundle together to form a persistent Z-ring; the ring constricts when completed.

Figure 3 ESCRT-based cell division in archaea. (a) Schematic of ESCRT-mediated cell division in archaea. CdvA polymers (orange) recruit CdvB protein (ESCRT-III: yellow) to the cytoplasmic side of the cell membrane. CdvA and CdvB interaction occurs through the C-terminal winged Helix like (wH) domain of CdvB. These two proteins together generate force, leading to constriction. The mechanism involves sliding of filaments. Upon completion of cytokinesis, the AAA-type ATPase Vps4 (pink) releases the ESCRT-III subunits. DNA is in blue and cell membrane is shown in gray. (b) Left: central section through cryotomogram of a dividing *Sulfolobus acidocaldarius* cell dividing using the ESCRT machinery. Right: segmentations of the same cell. Cell membrane is shown in green and the ESCRT belt is shown in yellow. Scale bar 200 nm (Dobro *et al.*, 2013). Localization of the ESCRT-III in *S. acidocaldarius*, as seen using fluorescence microscopy. Membrane is stained by FM4-64X (red) and ESCRT-III localization is visualized by antibody staining (green). Scale bar 1 μm (Samson *et al.*, 2008).

Structure of the Z-ring and Proposed Constriction Mechanisms

FtsZ protofilaments (Figure 2(f)) observed *in vitro* can be straight filaments, single or bundled, or can be curved to form arcs and mini-rings, especially in the presence of ADP. *In vivo*, parallel FtsZ filaments form the so-called Z-ring around the waist of the cell (Figures 2(b)–2(d)), thus defining the site of division and recruiting other proteins of the divisome complex. They are held in place near the membrane by binding dynamically to FtsA, ZipA, and other membrane-anchored proteins. Filaments may be cross-bridged and stabilized by accessory proteins such as ZapA or SepF. A complete ring of overlapping, though individually dynamic, FtsZ filaments have the ability to exercise a constrictive force. As the diameter of the ring decreases, the divisome complex inserts new peptidoglycan into the ingrowing cell septum.

FtsA, which is similar to actin family member MreB (described below), apart from the replacement of one subdomain by one in a different position, is essential for assembling the Z-ring on the cell membrane; the C-terminus of FtsZ binds to FtsA and the C-terminus of FtsA binds to lipid. The interactions are sufficiently dynamic to allow FtsZ filaments to treadmill (Loose and Mitchison, 2014), at least before there is any constriction of the Z-ring. FtsA has been shown to be capable of assembly into protofilaments itself. During initial establishment of the ring at mid-cell, the mismatch between subunit lengths in the two polymers will inhibit FtsA assembly but pairs of FtsA monomers may exert a tension on FtsZ filaments to favor curvature and thus help to orient the ring. However, some components of the divisome can only bind to FtsA that is not self-associating so, as the curvature increases and the difference in radii compensates more for the subunit mismatch, longer FtsA polymers become possible and more divisome components will be displaced; this may be important for finishing off the septum neatly.

Until very recently, the most popular theory for membrane constriction was an ‘iterative pinching’ mechanism involving nucleotide-dependent bending of membrane-tethered FtsZ protofilaments. However, it is now known that even protofilaments bound to non-hydrolyzable nucleotide cause some curvature on binding to membrane (Osawa and Erickson, 2011). Also the curvature seen for GDP-bound FtsZ (Li *et al.*, 2013) is in the wrong direction for FtsZ, when tethered by its C-terminus to FtsA (Szwedziak *et al.*, 2012), to be able to constrict the membrane from inside. Moreover, it has been seen that the individual filaments, which overlap to form a complete Z-ring, undergo continuous treadmilling rather than cycles of assembly, bending and disassembly. Constriction could be driven in a ring of treadmilling filaments if growth at plus ends were blocked at some stage while minus ends continued to shrink; filament-sliding in the direction that maximized filament-overlap should be more favorable than random sliding. The stress-response protein SulA that binds to the minus end of FtsZ may inhibit ring formation either by preventing treadmilling or by sequestering subunits.

Placement of the Z-ring at Mid-Cell

MinC and MinD are part of the system that prevents assembly of FtsZ filaments in the wrong places (Figures 2(e) and 2(f)) and thus ensures proper positioning of the Z ring for cell division. Close to either side of the proper Z ring, nucleoid occlusion factors on the surfaces of the pair of nucleoids protects them from being bisected by extra rings and, nearer the poles, the Min system prevents the formation of empty mini-cells. MinD, like other proteins in the WACA (Walker A Cytoskeletal ATPases) family (see below), undergoes ATP-dependent dimerization. In the case of MinD, this change also enables the protein to bind to membrane. MinC uses its

C-terminal domain to bind to MinD dimers and its N-terminal domain to inhibit the assembly of FtsZ into a ring. Alternating MinC/D dimers assemble on the membrane surface as bipolar filaments (Ghosal *et al.*, 2010). They bear some structural resemblance to eukaryotic septins. In Gram-negative bacteria, the effector protein MinE (not present in Gram positives)

displaces MinC and releases MinD from the membrane as ADP-bound monomers. Free MinD and MinC can then diffuse to the other pole. A long-lasting ring of MinE at mid-cell prevents binding there. Thus the Min proteins in species such as *E. coli* are observed to oscillate back and forth between the two available binding regions near the two poles. *In vitro*,

MinC/D/E mixtures, supplied with ATP, have been observed to bind in dynamic fashion to a lipid-coated surface, producing a variety of waves characteristic of reversible reaction-diffusion systems (Loose *et al.*, 2011).

ESCRT-Based Cell Division in Archaea

ESCRT-III filaments play a critical role in membrane budding and abscission in the eukaryotic endosome system for transporting membrane proteins between the plasma membrane, the *trans*-Golgi network and the lysosome/vacuole; related structures are found in archaea but not bacteria. In Crenarchaea and Thaumarchaea they are responsible for cell division. Proteins called CdvB, found in *Sulfolobus acidocaldarius* and *Nitrosopumilus maritimus*, have been investigated in particular. A protein called CdvA provides a link between the cell membrane and the CdvB filaments. The filaments have been visualized as cone-shaped spiral assemblies that appear to constrict the membrane between 2 daughter cells (Figure 3). The constriction mechanism is unknown but must involve some sliding of filaments. ESCRT-III filaments self-assemble but can only disassemble with the help of an AAA (ATPase associated with various cellular activities) protein called Vps4 (vacuolar protein sorting 4), which catalyzes dissociation of the ESCRT machinery from endosomal membranes. Vps4-like proteins are also present in the archaea.

DNA Segregation

After, and to some extent during, duplication, copies of chromosomal or plasmid DNA are separated to opposite halves of the mother cell by a variety of co-operating mechanisms. We focus here on those employing cytomotive filaments (Figure 4).

Segregation of Plasmids by Actin-Like ParM

Actin-family proteins that assemble free in the bacterial cytoplasm are involved in plasmid partitioning and include ParM,

AlfA and Alps1-6. Of these, the most well studied is ParM (Figures 1(c) and 4(b)), whose sequence and crystal structure are closer to known archaeal actin-like proteins than to bacterial MreB.

ParM/ParR/*parC* (ParMRC) (a 'type II' partitioning system) is responsible for the equal distribution of R1 plasmids in the daughter cells during cell division. The system has many parallels with TubZRC (a 'type III' partitioning system; Figures 1(b) and 4(a)). This is a clear example of convergent evolution, suggesting that bundles of double helical filaments are very good for distributing objects within a cell. Currently, ParMRC is the best understood cytomotive system in prokaryotes. Two ParM protofilaments form a left-handed double helical filament. Dynamic instability of ParM filaments assembling alone involves rapid filament formation and breakup, approximately 200 times faster than actin, allowing ParM to 'search' for plasmids. ParM filaments attached to plasmids, either captured or initiated *in situ*, grow steadily and more slowly. ParR is a protein that binds to a centromere-like region of the DNA (*parC*). The C-terminus of ParR binds to the barbed end of a ParM filament. Two or more ParM filaments associate side-by-side with mixed polarity to form a mitotic-spindle-like bundle with ParRC bound at each end and ParM filament elongation pushes the plasmids to opposite ends of the cell (cf. eukaryotic anaphase B). A curved polymer of ParR connecting each plasmid to its end of the growing spindle is functionally similar to a eukaryotic formins complex.

Segregation of Plasmids by Tubulin-Like TubZ

The plasmid-encoded TubZ protein (Figure 4(b)) found in *Bacillus* appears to be more closely related to archaeal CetZs than to FtsZ; CetZs are more similar to tubulins than FtsZs are. However, although the tubulin-like longitudinal contacts are preserved in TubZ (Figure 4(a)), a slight kink within each monomer produces a twist in an individual protofilament and paired protofilaments are superficially like the structure of F-actin. A pair of double filaments or bundle of 4 single protofilaments seem to be needed for activity in the TubZ/TubR/

Figure 4 Bacterial filaments involved in DNA segregation. (a) Top: schematic illustration of a type III plasmid partitioning system. This includes centromeric DNA linear repeats, followed by genes for a DNA binding adaptor and a tubulin-like motor. Below: structure of the active components; both TubZ and TubR dimer structures shown are from *Bacillus thuringiensis*. TubR polymer forms a helix on *tubC* DNA (Aylett and Löwe, 2012). TubZ monomer domains are colored according to the same rule as FtsZ in Figure 2(a). Monomers assemble into slightly twisted GTP-dependent protofilaments, which associate as two-stranded and four-stranded filaments. The latter, shown on the right, are thought to be active *in vivo* (Montabana and Agard, 2014). They seem to move plasmids by treadmilling, pulling a TubRC complex that maintains attachment at the shrinking end. At far right: super-resolution imaging of TubZ-GFP filaments in a *Bacillus sphaericus* cell (Ge *et al.*, 2014). (b) Top: schematic illustration of a type II plasmid partitioning system, which includes centromeric DNA linear repeats, a DNA binding adaptor and an actin-like motor. Below: the ParR dimer structure is from plasmid PB171 and the ParM dimer structure from *E. coli* R1 plasmid. ParR polymer forms a helix on *parC* DNA (Møller-Jensen *et al.*, 2007). The four subdomains typical of actin-family proteins are colored red, yellow, green and blue. The longitudinal interaction seen here between ParM monomers is conserved throughout the actin family. ParM forms ATP-dependent two-stranded helical filaments (right) that move ParRC by inserting subunits at the filament tip. Antiparallel filaments slide against each other as they grow, to push plasmids apart (Gayathri *et al.*, 2012). At far right: immunofluorescence micrograph of an *E. coli* cell carrying R1 plasmid. ParM is visualized in green using ParM-specific antibodies. Plasmids, labeled using the lactose operon LacI-lacO marker system, are shown in red. (c) Top: Schematic illustration of a type I plasmid partitioning system, which includes centromeric DNA linear repeats, a DNA binding adaptor and a WACA (Walker A Cytoskeletal ATPases) motor. Below: the ParB dimer structure is from *Enterobacteria phage P1* (PDB ID 1ZX4) and the ParA dimer structure is from *E. coli* P1 plasmid (PDB ID 3EZ6). ParA forms an ATP-dependent nucleoprotein filament, whose structure is shown (Hui *et al.*, 2010). The filament may work by transporting a plasmid attached to the end that shrinks during treadmilling. At top right: super-resolution imaging of ParA-eYFP (green) and CFP-ParB (red) in *C. crescentus* cells, showing DNA segregation (Ptacin *et al.*, 2010).

tubC plasmid partitioning system, in which it seems probable that shrinking TubZ filaments pull the replicated plasmids into the daughter cells (cf. eukaryotic anaphase A). TubR is a protein that forms a short curved polymer and binds to a centromere-like region of the DNA (*tubC*). The C-termini of TubZ interact with the TubR filament.

Segregation of Chromosomal DNA or Plasmids by WACAs

A large class of proteins known as WACAs (Walker A Cytoskeletal ATPases, having sequences that are placed in the 'P loop' superfamily but have a deviant Walker A motif) also use nucleotide-dependent polymerization (mostly on DNA/membrane) to carry out complex tasks. Their roles include chromosome segregation (Soj), plasmid segregation 'type I' (ParA; [Figure 4\(c\)](#)) or controlling the position of the Z-ring (MinD; [Figures 2\(e\)](#) and [2\(f\)](#)). They differ from actin and tubulin in forming bipolar filaments, as do eukaryotic septins. Many have a partner protein that is needed in activating the ATPase cycle. Plasmid ParAs bind non-specifically to nucleoid DNA in a nucleotide-dependent reversible way. The activating partner protein, ParB, with cargo attached (the centromere site *parS*, located on the plasmid) stimulates the ATPase cycle. ParA2 has been shown to form filaments *in vitro*; other ParAs may form filaments only on the nucleoid surface. Replicated plasmids may then be segregated by being transported over the surface by filament depolymerization. Alternatively, ParA dimers may bind all over the surface and dynamic relocation of each plasmid may be explained by a 'burnt bridge' molecular ratchet mechanism: interaction of the ParB/*parS* complex with a ParA dimer bound to the nucleoid would release the ParA monomers and the ParB/*parS* complex would then be free to bind to a neighboring ParA dimer. Even a random walk would tend to separate plasmid copies.

ParB binds tightly only to *parS* on the plasmid but other ParB dimers may associate with the complex and bind weakly to adjacent stretches of DNA. Spreading of the complex in 2 or 3 dimensions is thought to help the DNA to condense into a compact form, with SMC (structural maintenance of chromosomes) proteins being recruited once folding has begun.

Cell Shape Determination

Bacteria mostly have simple shapes, spheres, rods, plates, helices, and crescents; nonspherical cells depend on filaments associated with the membrane to maintain their shapes ([Figures 1\(d\)](#), [1\(e\)](#), and [5](#)). Motile cells have elongated shapes, usually with one or more flagella attached to one pole. Curved or helical shapes seem to be particularly good, both for swimming in liquid and for gliding over surfaces.

Actin-Like MreB in Rod-Shaped Cells

The longitudinal protofilament contacts between MreB subunits ([Figure 5\(a\)](#)) are almost identical to those of

polymerized actin but pairs of protofilaments are antiparallel, rather than parallel, and straight, rather than twisting around each other. MreB is found in all bacteria with elongated shapes and its filaments lie close to the cell membrane, in a similar manner to that of actin in the eukaryotic submembrane cytoskeleton. Besides constricting the cell into an elongated shape, MreB also organizes the elongasome complex, responsible for cell wall synthesis and cell growth, that inserts new peptidoglycan into the cell wall in a helical pattern ([Kawai et al., 2009](#)). Initial reports suggesting that these roles are achieved by a band of continuous MreB filaments stretching along the cell have been disputed; it seems most likely that individual filaments are normally short and dynamic but overlap to form short-lived continuous structures ([Figures 1\(d\)](#) and [5\(b\)–5\(d\)](#)). Continuous MreB structures are relatively more stable in the gliding bacteria (*Myxococcus*) ([Mauriello et al., 2010](#)). Association of MreB with the cell membrane is both direct and via accessory proteins such as RodZ.

Filamentous Proteins that Promote Curvature

A variety of filamentous proteins with long coiled-coil segments have been identified in different bacteria. Most, like lamin filaments in eukaryotic nuclei, seem to associate closely with membrane, in supporting and shaping roles. Some, like Crescentin in *Caulobacter crescentus* and AglZ in *Myxococcus xanthus*, extend along the whole cell length; others are found only at cell poles. Filaments of Crescentin, the first intermediate filament-like protein to be identified, produce the typical banana shape of *Caulobacter crescentus* by forming a membrane-stiffening band of polymers on one side of the cell ([Figures 5\(e\)](#) and [5\(f\)](#)); the series of coiled-coil domains resembles that of eukaryotic nuclear lamins and IF proteins such as Vimentin but no Crescentin atomic structure is currently available to confirm the similarity. Bactofilins are also predicted to form IF-like structures and are involved in the regulation of murein synthesis in *C. crescentus*. Normally, except when they are overexpressed ([Figure 5\(g\)](#)), they are restricted to the more curved regions of plasma membrane, at the cell poles. The DivIVA peripheral membrane protein, found in Gram-positive bacteria, is similar to the bar-domain proteins of eukaryotes and also locates to curved regions of membrane ([Figures 5\(h\)](#) and [5\(i\)](#)). DivIVA plays a role in locating MinCD to polar regions as well as promoting membrane curvature.

Many other filaments have been noticed in the cytoplasm of individual species and their functions are usually unknown. However, the presence of the enzyme CTP-synthase (CtpS), which forms filaments in eukaryotes as well as bacteria, affects the curvature of *C. crescentus* ([Figure 5\(f\)](#)).

Organization of Intracellular Membrane Compartments

Although there are no separate membranous organelles in bacteria, large intracellular compartments are often found, especially in more specialized bacteria. Cyanobacteria ('blue-green algae'), for example, have their photosynthetic

Figure 5 Cell shape determination by bacterial filamentous proteins. (a) Bacterial actin homologue MreB, with the four subdomains of a monomer colored red, yellow, green, and blue. The longitudinal interactions between monomers are as conserved throughout the actin family. MreB forms nucleotide-dependent flat antiparallel double filaments on membrane and maintains rod shape. Shown here are *Caulobacter crescentus* MreB dimer (left), and (AMPPNP) antiparallel double filaments (right) (PDB ID 4CZJ). (b) Central section through cryotomogram of a lipid tube decorated with *Thermotoga maritima* MreB and a corresponding subtomogram average, showing flat double filaments on the membrane (van den Ent *et al.*, 2014). (c) Organization of MreB filaments in *E. coli* cells. Fluorescence images of YFP-MreB showing (1) helical filaments and (2) band/ring-like structures (Vats and Rothfield, 2007). (3) GFP-MreB as small patches in *Bacillus subtilis* (Dominguez-Escobar *et al.*, 2011). (1,2) Copyright (2007) National Academy of Sciences, USA. (d) Summary: MreB filaments maintain a rod shape in many bacteria and deletion of the gene causes a distorted spherical cell shape. (e) Coiled-coil protein Crescentin (CreS) polymerizes along the length of the *C. crescentus* cell, causing higher strain on one side. This results in a bent cell shape. Cells lacking CreS grow with a straight rod shape. A combination of both Crescentin and CTP-synthase (CtpS) regulate cell shape in *Caulobacter*. (f) Section through tomographic reconstruction of *C. crescentus* showing CtpS filaments. Scale bar 100 nm (Ingerson-Mahar *et al.*, 2010). (g) Cryo-tomographic section of a *C. crescentus* cell overproducing Bactofilin, showing the extra filaments. Scale bar 50 nm (Kühn *et al.*, 2010). (h) Crystal structure of the *B. subtilis* peripheral membrane protein DivIVA (PDB ID 2WUJ). A composite model of the full-length protein has been made by combining N-terminal and C-terminal domain crystal structures (Oliva *et al.*, 2010). (i) Schematic of DivIVA localization in cells. During stationary phase DivIVA remains at the poles, while during exponential growth DivIVA localizes on the ingrowing septation (Bach *et al.*, 2014).

machinery embedded in extensive inward folds of the cell membrane. In other phyla, invaginations may be small and transient. The roles of bacterial dynamin-like proteins (BDLPs) are still unclear but it seems likely that they include the creation and maintenance of such membrane compartments. *In vitro*, BDLPs form polymers on lipid tubes (Figures 6(a) and 6(b)) like their eukaryotic counterparts.

Magnetotactic bacteria such as *Magnetospirillum*, have bag-like cell-membrane invaginations called magnetosomes that contain iron oxide or iron sulfide crystals (Figure 1(f)). MamK, a specialized actin-like protein, forms straight double filaments that organize a linear arrangement of magnetosomes to act as a magnetic field sensor (Figure 6(c)).

Conclusion

The cytoskeletons of prokaryotes are highly dynamic systems of proteins, of which the central components are cytomotive filaments, present in some form throughout all kingdoms of life. It is now clear that the cytoskeleton of the last common ancestor of all extant cells, including the 'simplest' bacteria, was already highly sophisticated. The properties of these filaments were so well adapted for intracellular movement that they have been conserved throughout subsequent evolution but, since the recruitment of different interacting proteins modulates the behavior of the conserved filaments, it is the explosion in the variety of regulatory factors and motor

Figure 6 Filaments involved in organization of intracellular membrane compartments. (a) Bacterial dynamin-like protein (BDLP) decorating a lipid tube, viewed in thin ice by electron cryo-microscopy. Scale bar 100 nm (Low *et al.*, 2009). (b) Top: 3D reconstruction of the BDLP/lipid tube, shown in cross-section. The arrangement of spokes that connect the globular GTPase domains to the membrane is simpler than in equivalent eukaryotic complexes. Bottom: model showing how BDLP assembles into left-handed helical filaments on lipid. Myosins

SM Heissler and JR Sellers, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

Coiled-coil A structural motif whereby α -helices from two different proteins associate to form a larger helix with a seven amino acid repeat.

Duty ratio The fraction of time during the ATPase cycle the motor spends attached on F-actin.

IQ motif An structural motif found in myosins and other proteins that binds calmodulin-like EF-hand family

member proteins. The consensus sequence is IQXXRGXXR.

Myosin A family of motor proteins which use the energy derived from ATP hydrolysis to interact with and move relative to actin.

Processivity The ability of a motor protein to take more than one step along F-actin per diffusional encounter.

Introduction

Myosins constitute a large multigene family of actin-based molecular motors, which are essential to eukaryotic homeostasis across the phylogenetic spectrum. Myosins are involved in growth and tissue formation, metabolism, reproduction, communication, reshaping, and movement of all 100 trillion cells in the human body. Further, myosins power the rapid entry of microbial pathogens such as parasites, viruses, and bacteria in eukaryotic host cells. In plants, essential processes like development, size control and cytoplasmic streaming are promoted by myosin motors.

These examples highlight the multifaceted functional activity of the myosin superfamily which is divided in 35 phylogenetic classes, including enzymatically inactive pseudoenzymes (Odronitz and Kollmar, 2007). In humans, the 39 myosin genes are categorized into 13 classes, as shown in Figure 1. Per definition, class-2 myosins which encompass the myosins involved in muscle contraction are referred to as 'conventional,' all other myosins as 'unconventional.' Despite myosin's functional diversity, all enzymatically active myosins couple the hydrolysis of ATP to force generation and unidirectional movement along filamentous actin (F-actin). This interaction, and consequently the mechanoenzymatic properties of the motor, is myosin specific and strictly fine-tuned by a plethora of up- and downstream effectors.

Myosin Structure and Organization

Myosins are heteromers composed of one or two myosin heavy chains and a variable number of calmodulin-like light chains. The myosin heavy chain is characterized by a prototypic motor domain, a neck region and a tail domain (Figures 2(a)–2(c)). Generally, the motor domain constitutes the N-terminus of the myosin heavy chain, but some myosins have N-terminal extensions of variable lengths preceding the motor domain (Odronitz and Kollmar, 2007).

The motor domain is highly allosteric and the catalytically active part of the molecule. It comprises of an ATP binding site and an F-actin binding region and links a repeated cycle of ATP hydrolysis to mechanical force generation on F-actin

(Figure 3), as outlined in greater detail below. The myosin motor domain core is highly conserved across phyla. Structural, kinetic, and functional diversifications are conferred by variable surface loops and the N-terminus. Surface loops are regulatory hotspots due to extensive phosphorylation, alternate splicing, and their implication in the establishment of the actomyosin interface (Lorenz and Holmes, 2010; Murphy and Spudich, 2000).

The α -helical neck domain comprises a variable number of light chain binding IQ motifs and can be lengthened by a monomeric stable single α -helix (Baboolal *et al.*, 2009). All characterized myosin light chains are calmodulin-like and comprise one to four EF-hand domains. As a central dogma, conventional myosins bind a light chain set composed of essential light chain (ELC) and regulatory light chain (RLC), whereas unconventional myosins bind the calcium-binding protein calmodulin. However, recent reports describe unconventional myosins as off-targets of the ELC and RLC (Guzik-Lendrum *et al.*, 2013; Lu *et al.*, 2014). Neck:light chain interactions increase the stiffness of the neck region, which allows the neck to function as a rigid lever arm during the force generating power stroke.

Myosin tail architecture is versatile due to a vast complement (>50) of domains and motifs such as coiled-coil domains, myosin tail homology 4/band 4.1, ezrin, radixin, and moesin (MyTH-FERM), postsynaptic density protein (PSD95), *Drosophila* disc large tumor suppressor (Dlg1), and zonula occludens-1 protein (zo-1) (PDZ) domain, src homology (SH) and pleckstrin homology (PH) domains (Figure 2(c)). Tail-domain variation is a crucial contributor to myosin-specific structural, regulatory, and functional properties as well as subcellular localization. For example, dimerization of myosins from classes-2, -5, and -18 is mediated by coiled-coil domains in the myosin tail. Solely the heavy chain of conventional class-2 myosins can further oligomerize and promote filament assembly. Additionally, tail domains establish the interaction with phospholipids and the complex number of myosin binding proteins (Sellers, 2000).

Bigger, faster, different – extreme diversification of the body plan of the myosin heavy chain is a prerequisite of the enormous functional activity of the myosome. The molecular weight of the heavy chain can vary from 94 to 495 kDa,

Figure 2 Structural domains found in typical myosins. (a) The myosin heavy chain has a motor domain (red) which harbors the nucleotide binding site and the F-actin binding region, followed by an IQ motif (orange) containing neck domain (gray) and a tail domain (dark gray). N- and C-terminal extensions (dashed line) for the myosin heavy chain are reported. (b) Three-dimensional model of the globular myosin motor domain (red). The light chains (orange, LC) bind to the IQ motifs in the α -helical neck region, distal from the motor domain. The nucleotide is represented in dark gray spheres. The F-actin binding region and the nucleotide binding pocket are indicated by an arrow. (c) Schematic diagrams of heavy chains of representative myosins from classes-1, -2- 5 and -7. Domains found in the myosin tails such as coiled-coiled and the myosin-5 globular, cargo binding tail domain (GTD) are colored in dark gray. The coiled-coil in the tail domain of nonmuscle myosin-2a and myosin-5a promotes the dimerization of the two heavy chains. Schemes are not drawn to scale.

faster than skeletal muscle myosin and more than 1000-fold faster than some myosins involved in the maintenance of the cytoplasmic architecture in animal cells (Higashi-Fujime *et al.*,

1995). In contrast, myosin-18 homologs and myosin-20 from the fruitfly *Drosophila* do not observably hydrolyze ATP and are immotile *in vitro* (Guzik-Lendrum *et al.*, 2013; Cao *et al.*,

Figure 3 (a) Kinetic cycle of actomyosin interaction during ATP hydrolysis: State 1: In the absence of ATP, myosin has a high affinity for actin and the lever arm is in a post-powerstroke state. State 2: Upon binding of ATP, the affinity of myosin declines ~ 1000 fold and myosin dissociates. State 3: Upon hydrolysis of ATP the lever arm recovers to the pre-powerstroke state and the myosin remains in a state ($ADP \cdot P_i$) with weak affinity for actin. State 4: Upon release of P_i the myosin affinity for actin increases and myosin is strongly bound with the lever arm in the pre-powerstroke configuration. The powerstroke is associated with the events involved in ADP release. (b) Schematic comparison of the lever arm conformation in the pre- and the post-power stroke state. The lever arm rotates around 60° during the hydrolysis cycle and results in a lateral displacement of the myosin motor domain on F-actin. With the exception of unconventional myosin-6 which moves toward the (-) end of F-actin, all other myosins move to the (+) end of the filament.

2014). The kinetic tuning likely coincides with myosin function. Fast kinetics is required for contracting a skeletal muscle fiber or for transporters that move cargos over long distances in cells. In contrast, the kinetics of some myosins are more adapted to a role as an F-actin tether that is able to maintain force for long periods of time with less energy usage.

Apart from kinetic and structural signatures of the heavy chain, myosins operate under different regimes to increase the

functional diversity: As monomers, dimers, or multimers. Monomeric myosins are associated with tethering functions on F-actin but in some cases can be rendered into dimers by external or internal cues such as cargo-induced oligomerization or clustering. Dimeric motors such as class-5 and -11 myosins are efficient transporters, which move cargoes like organelles, vesicles, and RNA along the actin cytoskeleton. Uniquely, class-2 myosins assemble into higher order sidepolar or

bipolar filamentous arrays consisting of 14–300 motors (Billington *et al.*, 2013).

Mechanochemical ATPase Cycle

The mechanochemical actomyosin ATPase cycle is conserved in all enzymatically active myosins. The basic concept of the cycle are antagonistic affinities for ATP and F-actin, as shown in the Lymn–Taylor cycle (Figure 3; Lymn and Taylor, 1971). Myosin strongly binds to F-actin in the absence of nucleotide (state 1). This state is also referred to as rigor state. ATP binding causes the dissociation of the actomyosin complex (state 2). ATP hydrolysis occurs in the actin-detached state and is associated with a lever arm rotation, the recovery stroke. In the posthydrolytic ADP.Pi state, myosin weakly rebinds to F-actin (state 3). The subsequent P_i-release is associated with small conformational changes in the myosin motor domain, which are transmitted to the neck region, which functions as a rigid lever during its force producing swing. This power stroke produces effective displacement of the myosin.ADP complex on F-actin and shifts the myosin to a strong F-actin binding state. ADP-release transitions the motor back to the rigor state, in which the cycle repeats (state 4). Similar to Archimedes' law of the lever, the length of the myosin lever arm positively correlates with the displacement of the motor. With the exception of class-6 myosins, which move toward the pointed (–) end, all myosins characterized so far traffic toward the barbed (+) end of F-actin (Figure 3(b)).

The fraction of time the myosin spends in the strong actin-binding states (A.M and A.M.ADP) is the 'duty ratio' – a measure for the functional capacities and limitations of a motor (De La Cruz and Ostap, 2004; Bloemink and Geeves, 2011). Processive myosins which take multiple steps before detaching from F-actin are characterized by a high duty ratio (>0.50). A prototypic example for a high duty ratio motor is the double-headed unconventional myosin-5a, which functions as an effective cargo transporter because one head is in continuous interaction with the F-actin track. By contrast, a single-headed myosin, such as skeletal muscle myosin-2 with a low duty ratio of 0.02 must work in arrays composed of >300 heads to maintain continuous interaction with the F-actin. Additionally, single-headed myosins can work in small ensembles such as clusters on, for example, cargo vesicles to ensure bona fide transport function. Based on the mechanokinetic signatures, myosins are categorized in four different classes: fast movers, slow/efficient force holders, strain sensors, and processive motors (Bloemink and Geeves, 2011). Catalytically inactive pseudoenzymes such as class-18 and -20 myosins form a separate group.

Pathophysiology

Mutations, malfunction, and dysregulation of myosins are associated with heterogeneous pathophysiological conditions in mammals like cardiomyopathies, cancer, blindness, diabetes, deafness, and blood disorders. The mutational spectrum on the genes encoding for the myosin heavy chain and the associated light chains contain hundreds of mutations. Well-

studied examples include cardiac myosin-2 heavy chain gene mutations which result in cardiac disorders associated with aberrant cardiac muscle function and the impact of mutations in conventional and unconventional myosins in multi-spectrum disorders associated with congenital and progressive vision and hearing impairment (Petit and Richardson, 2009; Mansson, 2014; Spudich, 2014).

Due to the involvement of the myosome in processes such as the organization of the mitotic spindle, cytokinesis, and cell migration, myosin malfunction can cause various cancer types, including prostate cancer, where enhanced carcinogenesis and metastasis are linked to increased myosin-6 levels (Puri *et al.*, 2010). Malfunction or ablation of the tumor suppressor nonmuscle myosin-2a is associated with a predisposition to squamous cell carcinomas with poor survival (Schramek *et al.*, 2014). Nonmuscle myosin-2a is also linked to blood disorders and associated syndromic phenotypes (Ma and Adelstein, 2014). Other diseases are associated with myosin's function as cargo transporters and can result in cases where physiological cargoes cannot be delivered appropriately. A prototypic example is the pigment dilution of skin and hair due to impaired transport of melanosomes in melanocytes by myosin-5a (Wu *et al.*, 1997). Utilization of the actomyosin transport system by non-physiological cargoes such as viruses facilitates host cell entry, transport, and viral egress (Schudt *et al.*, 2013; Arii *et al.*, 2010; Roberts and Baines, 2010; van Leeuwen *et al.*, 2002). Indirectly, parasite myosins cause a broad-range of both zoonotic and non-zoonotic diseases with medical and veterinary importance along with high economic impact. Because of the plethora of myosin-dependent functions, pharmacotherapeutic bench to bedside approaches will be a substantial part of translational myosin research in the future.

Class-1 Myosins

Class-1 myosins are very abundant across phylogeny and the first class of unconventional myosins discovered 41 years ago (Pollard and Korn, 1973). Class-1 myosins are small, monomeric motors which control membrane tension and dynamics by acting as crosslinkers between the F-actin cytoskeleton and the latter. Crosslinking properties are mediated by phospholipid binding tail homology (TH) domains and F-actin binding properties of the motor domain. Based on the tail domain, class-1 myosins can be classified as short and long-tailed. Short-tailed class-1 myosins have a TH1 domain in their tails whereas long-tailed class-1 myosins harbor additional domains that can mediate protein–protein interactions or ATP-insensitive F-actin binding (McConnell and Tyska, 2010).

Class-1 myosins are involved in pathophysiological relevant tasks such as the transport of glucose transporter GLUT4 containing vesicles or organelles. Further, they mediate mechanosensory functions of sensory hair cell stereocilia and play pivotal roles in hematopoietic cells where they modulate immune functions (Bose *et al.*, 2002; Gillespie 2004; Santos-Argumedo *et al.*, 2013). Further, class-1 myosins might play a role in the regulation of RNA polymerase 1, transcription, and cell cycle progression in the nucleus (Ye *et al.*, 2008; Sarshad *et al.*, 2013; Percipalle *et al.*, 2006).

Class-2 Myosins

Citius, Altius, Fortius: Ubiquitous class-2 myosins constitute one of the largest subfamilies with up to 22 myosins per vertebrate organism (Odrionitz and Kollmar, 2007). Class-2 myosins are hexameric, consisting of a myosin heavy chain homodimer that non-covalently associates with a set of ELC and RLC. A tail coiled-coil domain mediates homodimerization. Uniquely, conventional myosins form filaments with characteristic signatures: Sarcomeric class-2 myosins from striated and cardiac muscle ensemble into bipolar filaments consisting of ~400 myosins and form the thick filaments that – together with actin thin filaments – assemble into parallel, highly stereotyped sarcomeres which cause the striped pattern of muscle. At the molecular level, sarcomere shortening and hence muscle contraction occurs when thick myosin filaments and thin actin filaments slide past each other.

Mammalian smooth muscle does not form precise sarcomeres and instead their myosins assemble into side-polar filaments consisting of hundreds of myosin molecules (Xu *et al.*, 1996). In contrast to sarcomeric myosins, these filaments continuously assemble and disassemble (Seow, 2005). Phosphorylation of the associated RLC by calcium/calmodulin-dependent myosin light chain kinase or dephosphorylation by myosin phosphatase acts as on/off switch for myosin's catalytic activity. In the absence of RLC phosphorylation, smooth muscle myosin adopts an autoinhibited, compact 10S conformation and adopts an extended 6S conformation upon RLC phosphorylation which readily assembles into filaments (Dulyaninova and Bresnick, 2013). Similar regulatory features are described for cytoplasmic nonmuscle myosin-2 paralogs. As the closely related myosin from smooth muscle, nonmuscle myosin-2 adapts a compact, autoinhibited conformation in the absence of RLC phosphorylation. Nonmuscle myosin-2 paralogs are regulators of spatiotemporal cytoskeletal dynamics during essential processes such as cell migration, adhesion, and cytokinesis and form short bipolar filaments with an average of 14–30 molecules (Billington *et al.*, 2013; Vicente-Manzanares *et al.*, 2009; Heissler and Manstein, 2013). In contrast to conventional myosins from smooth and skeletal muscle, the three nonmuscle myosin-2 paralogs found in mammalian cells have a vast tissue distribution and are expressed in a developmentally dependent manner. Though their kinetic features are related, functional activity is non-redundant but overlapping may occur (Vicente-Manzanares *et al.*, 2009).

Class-3 and -9 Myosins

Class-3 and -9 myosins have dichotomous functions as actin-based motor proteins and signaling molecules. Class-3 represents small monomeric myosins that harbor an N-terminal kinase domain prior to the motor domain. The kinase domain confers serine/threonine kinase activity and implicates a function for class-3 myosins in intracellular signaling. Autophosphorylation has been reported for class-3 myosins, though other protein targets for the kinase domain have not been identified (Dalal *et al.*, 2011). Class-3 myosins are implicated in the function of ciliary hair cells and retinal

photoreceptors. In mammals, mutations of *MYO3A* lead to deafness (Walsh *et al.*, 2011). In *Drosophila*, the myosin-3 analog NINAC plays a crucial role in phototransduction and rhabdome maintenance (Porter *et al.*, 1992). In mammals, class-3 myosins have been proposed move along parallel F-actin bundles. In myosin-3a, this motility is thought to be conferred by a second F-actin binding site in the tail domain, which allows the motor to be in continuous interaction with its track (Les Erickson *et al.*, 2003). Conversely, myosin-3b lacks the respective site and associates with binding partners such as espin-1 that harbor an actin binding site for facilitated motility (Merritt *et al.*, 2012).

Signaling activity is also reported for class-9 myosins, which are processive, single-headed molecular motors exclusively found in animals. Invertebrates contain one class-9 myosin, mammals two. Myosin-9a functions in the regulation of epithelial cell morphology, differentiation, and migration (Abouhamed *et al.*, 2009; Omelchenko and Hall, 2012). Distinctively, myosin-9b regulates shape and motility of immune cells, a crucial function during the immune response (Hanley *et al.*, 2010). The myosin-9 heavy chain has three structural signatures: A N-terminal extension with a pseudo Ras-binding domain, an unusual long surface loop in the myosin motor domain that contains a calmodulin binding site and a tail domain which contains a Rho GTPase-activating protein (Rho-GAP) domain (Bahler *et al.*, 2011). The latter increases the GTPase activity of members of the Rho family such as RhoA and Cdc42, which are regulators of cytoskeletal dynamics and cell cycle, thereby negatively regulating the Rho signaling pathways. The presence of a characteristic myosin motor domain and Rho-GAP domain enables myosin-9 to function dichotomously as molecular motor and signaling molecule, regulating and organizing the actin cytoskeleton at the same time (Bahler *et al.*, 2011). The long surface loop in the myosin motor domain has been shown to facilitate processive motion of the single-headed myosin by acting as an electrostatic tether, a unique feature of class-9 myosins (Elfrink *et al.*, 2014).

Class-5 Myosins

Class-5 is the best understood myosin class and expressed in most eukaryotes except plants – where class-8 and -11 myosins have a similar functional and structural features. Class-5 myosins are dimeric, short-range cargo transporters, and dynamic organelle tethers. Cargos range from mRNA to organelles such as the endoplasmic reticulum and pigment granules (Wu *et al.*, 1997; Wagner *et al.*, 2011; Yoshimura *et al.*, 2006). Dimerization via a coiled-coil forming sequence paralleled by mechanochemical characteristics like a high duty ratio support a processive stepping motion on actin filaments and bundles – a prerequisite for efficient cargo transport. Myosin-5 dimers walk in a hand-over-hand fashion on F-actin, taking multiple 36 nm steps which match the 36-nm F-actin pseudorepeat (Mehta *et al.*, 1999). During processive movements, the two heads of a myosin-5 bind 36 nm apart on an actin filament defining a leading and trailing head. It is likely that both heads are in an ADP-bound state during these dwells (Walker *et al.*, 2000). Intramolecular strain results in the dissociation of ADP from the trailing head, shifting it into the rigor state.

Subsequently, ATP binding to the trailing head results in its dissociation from F-actin, thereby triggering the leading head to undergo a power stroke which positions the new leading head (in the ADP.Pi state) to a forward F-actin binding site. The new leading head releases Pi and binds strongly to F-actin, thereby returning to the starting point of the mechanoenzymatic cycle, but translating 36 nm forward on F-actin (Sakamoto *et al.*, 2008). Processivity, the ability to make multiple steps before detaching from its tack, and run length of class-5 myosin is further determined by binding partners which function as regulatory switches for myosin-5: In the absence of cargo, myosin-5 adopts an autoinhibited conformation in which both heads fold back on the tail domain. The backfolded conformer is kinetically inert, preventing futile ATP consumption (Sellers and Knight, 2007). Cargo-loading is associated with an unfolding of myosin from an autoinhibited conformation and rendering the motor to an efficient transporter (Wu *et al.*, 1997; Sellers and Knight, 2007; Skolnick *et al.*, 2013).

Class-6 Myosins

Myosin-6 is the sole myosin identified so far that moves toward the pointed (–) end of F-actin (Figure 3(b)). Direction-reversal is caused by a unique insert located between the myosin motor domain and the neck region. The insert binds calmodulin and redirects the lever arm respective to the myosin motor domain (Menetrey *et al.*, 2005). Myosin-6 is involved in various cellular processes such as endo- and exocytosis, cell migration, the maintenance of Golgi morphology, and cancer cell metastasis (Puri *et al.*, 2010; Sahlender *et al.*, 2005; Tumbarello *et al.*, 2013; Buss and Kendrick-Jones, 2008). Recent work indicates a modulatory function for nuclear myosin-6 in RNA polymerase 2 dependent transcription regulation (Vreugde *et al.*, 2006). The interaction between the myosin tail domain and specific adapter and cargo proteins mediates the vast physiological tasks as F-actin tether or processive transporter. Further, the interaction of myosin-6 and its binding partners changes the mechanoenzymatic properties of the motor: Cargo-free myosin-6 is a nonprocessive monomer with actin tethering properties whereas the cargo-bound dimer acts as processive transporter (Yu *et al.*, 2009; Buss *et al.*, 2004; Lister *et al.*, 2004).

Class-7, -10, and -15 Myosins

MyTH-FERM myosins is a collective term for myosin classes-7, -10, and -15. Those myosins share the conserved dyad of a MyTH4 domain followed by a FERM domain in their tails, suggesting a close phylogenetic and functional relationship. The light chain content and the oligomeric state of MyTH-FERM myosins are still controversial. Among MyTH-FERM myosins, myosin-10 is ubiquitously expressed whereas class-7 and -15 myosins are often targeted to sensory organs and the endocrine system (Lloyd *et al.*, 2001; Hasson *et al.*, 1995; Berg *et al.*, 2000). A common signature of MyTH-FERM myosins is their localization to parallel actin-rich structures as they are found in stereocilia, microvilli, and filopodia (Kerber and

Cheney, 2011; El-Amraoui and Petit, 2005; Hartman *et al.*, 2011; Lu *et al.*, 2014).

Myosin-7a is implicated in vision and hearing in mammals and *Drosophila* and mutations in MYO7A associated with multisystem disorders characterized by deafness and retinal degeneration (Weil *et al.*, 1995). In the eye, myosin-7a localizes to the retinal pigmented epithelium where it is required for the visual retinoid cycle and the transport of opsin, phagosomes, melanosomes, and vesicles of the endoplasmic reticulum along with microtubule motors (Lopes *et al.*, 2011; Gibbs *et al.*, 2004). In the densely packed F-actin-rich structures in sensory hair cell stereocilia, myosin-7a plays a pivotal part in the mechanotransduction complex, serving in tip-link tensing and the maintenance of stereocilia structure (Grati and Kachar, 2011).

Myosin-15a is the largest heavy chain due to a long N-terminal proline-rich extension without recognizable motifs. The function of the extension is unknown, however, mutations in the domain are linked to congenital deafness in humans (Liang *et al.*, 1999). Myosin-15a is a critical determinant for stereocilia elongation, maturation, and the formation of the staircase-like architecture (Belyantseva *et al.*, 2003, 2005). Furthermore, myosin-15a is part of the stereocilia elongation complex and transports cargos such as the scaffolding protein whirlin to the tip of hair cell stereocilia (Belyantseva *et al.*, 2005).

Myosin-10 functions in pseudopod extension during phagocytosis in macrophages (Cox *et al.*, 2002). Myosin-10 localizes to the tips of filopodia and is significant for filopodial dynamics, formation, and intrafilopodial motility (Bohil *et al.*, 2006; Berg and Cheney, 2002). The myosin-10 MyTH4 domain was shown to bind microtubules, suggesting myosin-10 to be an integrator of the F-actin and microtubule cytoskeleton (Weber *et al.*, 2004).

Class-8 and 11 Myosins

Class-8 and -11 represent large multigene families and are the sole plant specific myosins. Class-8 myosins are involved in new cell wall formation, endocytosis, cell–cell transport and communication through plasmodesmata (Tominaga and Nakano, 2012). In moss, myosin-8 is required for bona fide protonemal patterning and development. Ablation of all class-8 myosins is associated with growth defects and cell expansion (Wu *et al.*, 2011). The action of the actomyosin cytoskeleton on plasmodesmata and intracellular movement is of particular interest since plant viruses such as tobacco mosaic virus and grapevine fanleaf virus hijack the actomyosin cytoskeleton for intracellular transport and cell-to-cell spreading of the viral infection (Kawakami *et al.*, 2004; Amari *et al.*, 2011; Harries *et al.*, 2009). Hijacking of the actomyosin cytoskeleton by plant viruses causes severe loss in crop yields worldwide and has a high socio-economic impact.

Structure follows function: Class-11 myosins are morphologically similar to mammalian class-5 myosins and involved in fast intracellular trafficking of organelles and vesicles such as chloroplasts, mitochondria, the endoplasmic reticulum, and peroxisomes. Organelle-associated myosin-11 is involved in cytoplasmic streaming, a form of directed, active actin-based

flow of the cytoplasm, and organelles in cells from algae to higher plants. In the alga *Chara*, myosin-11 propels F-actin with a velocity of $50\text{--}60\ \mu\text{m s}^{-1}$ – making it the fastest myosin motor characterized so far (Higashi-Fujime *et al.*, 1995). Studies with chimeric myosins suggest that the myosin-based cytoplasmic streaming is a determinant of plant size in *Arabidopsis*, implicating a potential future application in artificial size control in plants (Tominaga *et al.*, 2013). In *Arabidopsis*, simultaneous knockout of the three essential class-11 myosins that are responsible for organelle transport results in plant-development and fertility defects (Ojangu *et al.*, 2012). Ablation of both class-11 myosins in moss indicates their function the establishment of cell polarity and growth (Vidali *et al.*, 2010).

Class-14 Myosins and -21 Myosins

Class-14 myosins are specific to protozoan apicomplexan parasites such as *Plasmodium* and *Toxoplasma* which cause malaria and toxoplasmosis, respectively. Myosin-21 is found in *Leishmania*, a trypanosomatid which is responsible for leishmaniasis in humans. Structurally, class-14 myosins are atypical by lacking consensus IQ motifs and having a very short tail domain. The actomyosin cytoskeleton plays an integral part in locomotion, host cell invasion and infection of apicomplexan invasive stages (Kappe *et al.*, 2004). Apicomplexan parasites actively use a gliding motility for host cell entry, which relies on the parasite substrate-dependent actomyosin-mediated gliding motility, which pushes the parasite in the host cell – independent from the host cell cytoskeleton (Matuschewski and Schuler, 2008). Despite a highly degenerated IQ motif and the absence of a tail domain, class-14 myosins bind light chains, which contribute to both, gliding motility and invasion and uniquely anchor the myosin to the plasma membrane (Polonais *et al.*, 2011).

Myosin-21, which plays a role in the assembly of the flagellum and intracellular trafficking, has the distinguishing feature to undergo a light chain mediated dimerization (Batters *et al.*, 2014; Katta *et al.*, 2009, 2010). Calmodulin binding to the neck region prevents dimerization of the monomeric heavy chain, calmodulin dissociation its dimerization. Uniquely, the presence of calmodulin is paralleled by the ability of the motor to bind phospholipids and to power motility. Its absence renders myosin-21 an immobile actin-crosslinker that is unable to bind lipids (Batters *et al.*, 2014).

Class-16 and -18 Myosins

Class-16 myosins are single-headed motor proteins characterized by a large N-terminal ankyrin repeat domain which associates with the catalytic subunits PP1 α and PP1 γ of protein phosphatase 1 (Patel *et al.*, 2001). Myosin-16b localizes throughout the cytoplasm and the nucleoplasm, excepting the nucleolus. The nuclear expression of myosin-16b is cell cycle dependent and plays a pivotal regulatory role in its progression (Cameron *et al.*, 2013). Nucleolar import is mediated by the myosin tail domain (Cameron *et al.*, 2007). Apart from class-16 myosins, nuclear localization is solely described for

myosin -1c, -2, -5a, and -5b, myosin-6, -9b, -10, and 18b (de Lanerolle, 2012).

Class-18 myosins are exclusive to metazoan and are catalytically inactive pseudoenzymes. Myosin-18a dimerizes via an extended coiled-coil in the tail domain and assembles into dimeric structures, similar to conventional myosin-2. Additionally, unconventional class-18 myosins bind ELC and RLC as light chains (Guzik-Lendrum *et al.*, 2013). Even though there is a high degree of overall structural similarity with conventional class-2 myosins, filamentation is not reported for class-18 myosins. Myosin-18a isoforms have a long N-terminal extension which contains a PDZ domain and an ATP-insensitive F-actin binding site, though overall, the motor has a very low affinity for F-actin (Mori *et al.*, 2005). Sequence alignments highlight that conserved structural elements in the nucleotide binding pocket are altered, which might be the cause of the comprised catalytic activity (Guzik-Lendrum *et al.*, 2013). The same might be true for class-16 myosins suggesting that their physiological role is structural rather than catalytic. A physiological role of myosin-18a as binding partner of the PAK2/betaPIX/GIT1 complex suggests a potential function in modulating epithelial cell migration (Hsu *et al.*, 2010). Moreover, myosin-18a might be implicated in the maintenance of Golgi morphology and myogenesis (Bonn *et al.*, 2013; Dippold *et al.*, 2009).

Class-19 Myosins

Myosin-19 is a small monomeric, vertebrate specific myosin with a high duty ratio that traffics to the plus-end of F-actin. Interestingly, it binds the RLC as light chain and but its phosphorylation has no significant effect on the mechano-enzymatic motor properties (Lu *et al.*, 2014). Myosin-19 localizes to mitochondria and might be actively involved in mitochondrial positioning and transport in vertebrate cells (Quintero *et al.*, 2009).

Summary and Perspectives

The physiological tasks myosins are involved in are as versatile as the family members. Present in almost all eukaryotes, myosin motors are extensively required in all aspects of life. Actomyosin-driven contractility is indispensable during embryogenesis, development, and the maintenance of essential bodily functions in the adult organism including motile and sensory functions. At the single molecule level, myosin motors actively define the cytoplasmic architecture and transport cargos such as vesicles, mRNA, and organelles along the actin cytoskeleton to their destination in a spatiotemporal and developmentally dependent manner. Myosin malfunction – caused, for example, by mutations or misregulation – can cause severe disorders such as cardiomyopathies and cancer. Further, parasite- and virus-borne diseases often rely on the parasitic or host cell actomyosin cytoskeleton for invasion. As different as they are, all myosins share a common motor domain that interacts with ATP and F-actin – though the rates and affinities vary considerably. Structural diversity around the motor domain, particularly seen in the myosin tail domain

and both termini confer different regulatory and functional signatures. Those differences, paired with individual kinetic features, render individual myosin motor for its particular, physiological functions.

Despite an increasing number of characterized family members of different classes, the molecular mechanism underlying ATP hydrolysis and mechanotransduction as well as regulatory aspects of myosin motor function are only beginning to be understood. This is especially true for the recently identified and characterized mammalian and parasitic unconventional myosins, where information about the mechanoenzymology, oligomerization state, binding partners, and physiological functions in the molecular architecture of the cytoskeleton remain largely elusive. As research continues, the answers about the dynamics of a single myosin in time and space will be elucidated in *in vitro* and *in vivo* and substantially contribute to our understanding of physiological and aberrant myosin function in health and disease. Translational structural, pharmacological, and clinical approaches will lead to the development of myosin-specific drugs. The compound-mediated alteration of actomyosin-driven contractility or the myosin:binding partner interaction will be a milestone for basic research and the future treatment of myosin-related diseases.

Glossary

Cilia/flagella Microtubule-based cellular protrusions that function in the generation of fluid flow and signal transduction.

Glutamate receptors Major neurotransmitter receptors of excitatory neurons; involved in synaptic plasticity; classified into ionotropic receptors (including NMDA, kainite, and AMPA receptors) and metabotropic receptors.

Intraflagellar transport Bidirectional transport within cilia/flagella using the microtubule motors kinesin-2 (KIF3) and cytoplasmic dynein 2; involved in ciliogenesis and other ciliary functions.

Microtubules A major cytoskeletal component; 25-nm diameter tubular filaments consisting of alpha- and beta-tubulin heterodimers; the faster-growing plus ends generally point to the cell periphery.

Molecular motors Enzymes that generate motile force by utilizing the chemical energy from the hydrolysis of ATP into ADP and Pi.

Ventral node An embryonic endomesodermal ventral midline organ essential for left–right determination; the rapidly rotating cilia on its surface generate a leftward fluid flow that initially breaks the lateral asymmetry (nodal flow).

Introduction

Recently Emerging Concept of Intracellular Transport

Similar to railway cargoes connecting the center and the periphery of a country, intracellular transport connects the center and the periphery of the cell and plays a critical role in cellular function. Because the semantics of biological molecules vary considerably in different locations, the excess or deficiency of such molecules, including enzymes, receptors, signal transduction components, and structural molecules, at a specific site leads to serious abnormalities in cellular functions that may cause systemic diseases. Kinesins are molecular motors that are largely responsible for transporting these critical cargos along the microtubule tracks in order to properly localize these cargos within the cell. Some kinesins also serve for microtubule dynamics, mitosis and meiosis, intraflagellar transport, and signal transduction. This concept of intracellular transport has been gradually accepted by a wider audience, thanks especially to real-time visualization via the innovative technology of time-lapse microscopy, which can clearly resolve the directional and nondirectional movements of macromolecular complexes and organelles within cells.

Axonal transport in neurons is one of the best studied examples of intracellular transport. It plays a key physiological role in maintaining the structure and function of both the central and peripheral nervous systems. Astonishingly, neuronal axons, sometimes up to 1 m long, for the most part do not contain protein synthesis machinery. Thus, most of the essential proteins, macromolecular complexes, and lipids that are essential for neuronal axon function are synthesized at the cell body and are transported to axons by kinesins.

Discovery of Kinesin and Kinesin Superfamily Proteins

In a historic metabolic labeling experiment of eyeballs, protein transport toward optic nerve axons was classified into several categories, including fast and slow axonal transport ([Grafstein and Forman, 1980](#)). These transport mechanisms function at maximum speeds of 240 mm per day (group I), 34–68 mm per day (group II), 4–8 mm per day (group III), 2–4 mm per day (group IV, slow component b), and 0.7–1.1 mm per day (group V, slow component a). Structural proteins and metabolic enzymes are primarily transported by the slow mechanisms, while membrane organelles are primarily transported by the fast mechanism. High resolution electron microscopy described short filamentous structures, which are probable candidates for motor proteins that link microtubules to organelles ([Hirokawa, 1982](#)). In fact, conventional kinesin, now defined as kinesin-1 holoenzyme, was identified in 1985 via biochemical purification ([Brady, 1985](#); [Vale et al., 1985](#)) as one of the enzymes that is responsible for anterograde fast axonal transport along the microtubule cytoskeleton. One kinesin-1 holoenzyme consists of two kinesin heavy chains (KHCs; KIF5A, 5B, or 5C) that display microtubule-activated motor ATPase activity and two kinesin light chains (KLCs) that serve as cargo connectors. Later, MAP1C, also referred to as cytoplasmic dynein, was identified as a major retrograde motor ([Paschal et al., 1987](#)). We first visualized purified kinesin-1 molecules via electron microscopy, resulting in an appearance that was identical to the organelle-microtubule cross-linking structure in axons that were specifically decorated by anti-kinesin-1 antibodies ([Hirokawa et al., 1989](#); [Figure 1](#)).

The physiological relevance of kinesin-1 in intracellular transport was revealed by genetics studies of fungi, *Drosophila* ([Hurd et al., 1996](#)), and mice ([Tanaka et al., 1998](#)). For example, kinesin-1 depletion via gene targeting in mice revealed

Figure 1 Structures of kinesin *in vitro* and *in vivo*. (a) High magnification image of rotary-shadowed kinesin. One or two globular domains are visible at the right end of each molecule, whereas less well-defined, but generally fan-shaped, domains can be detected at the opposite ends. (b) Quick-freeze, deep-etch electron micrograph of rat brain neurites. Many of the cross-bridges contain globular bulges where they appear to contact microtubules (see arrows). Bars, 100 nm. Reproduced with permission from Hirokawa, N., Pfister, K.K., Yorifuji, H., *et al.*, 1989. Submolecular domains of bovine brain kinesin identified by electron microscopy and monoclonal antibody decoration. *Cell* 56, 867–878.

striking perinuclear clustering of its mitochondrial cargo in extra-embryonic yolk sac cells (Tanaka *et al.*, 1998). This perinuclear clustering was proposed to be due to an imbalance of bidirectional transport in these cells, providing genetic evidence that kinesin can significantly alter the intracellular localization of organelles. Concurrently, positional cloning of yeast and fungal cell division mutants revealed the existence of kinesin-like proteins that shared several amino acid sequences with kinesin-1, such as KAR3 in yeast (Meluh and Rose, 1990). Based on RT-PCR cloning using degenerate primers corresponding to consensus sequences from a mouse brain cDNA library, our group first identified all 45 genes for the mammalian kinesin superfamily proteins (KIFs) (Miki *et al.*, 2001; Nakagawa *et al.*, 1997; Aizawa *et al.*, 1992).

Strategies in Kinesin Biology

Elucidating the structure and function of KIFs became the next focus of intracellular transport research (Goldstein, 1993; Hirokawa, 1998). Because KIFs are thought to bind to their specific cargos directly or via adaptor/scaffold molecules, the identification of specific cargos and their adaptors and scaffolds via molecular cell biology has been the most powerful approach to determine the specific intracellular roles of KIFs, together with analyses of genetic loss- or gain-of-function mutations. This approach has resulted in the occasional identification of human KIF genes that are responsible for systemic diseases and anomalies via positional cloning of hereditary disease pedigrees, for which exome sequencing represents a powerful tool. Another important question in KIF biology is how these motors are able to move forward (or backward or to perform atypical functions) using the chemical energy of ATP. Together with sophisticated biochemistry and biophysics, structural biology has been used to address this question, providing a rough outline of the activity of the engine of this remarkable mechanochemical ATPase (see Further Readings). From this perspective, in this article, we will briefly summarize the major findings and unresolved questions in kinesin biology.

Molecular Phylogeny and Nomenclature of Kinesins

A standardized kinesin nomenclature and classification system was developed after several rounds of discussions (Lawrence *et al.*, 2004). All mammalian kinesins, which are defined as those molecules which contain kinesin motor domains, follow the KIF numbering system. However, those proteins which contain a KIFC consensus sequence, which drives the motor toward microtubule minus ends, are assigned KIFC numbers. These kinesins are phylogenetically classified into subfamilies from kinesin-1 to kinesin-14, each of which often comprises a separate functional entity, as summarized in Figure 2. Kinesins 1–12 are classified as N-kinesins, which generally contain a microtubule-plus-end-directed motor domain in the N-terminus of the molecule. This group includes atypical non-motor kinesins, such as kinesin-11, which functions in signal transduction. Kinesin-13 (M-kinesin, or Kin I), whose motor domain lies in the middle of the molecule, depolymerizes microtubules. Kinesin 14 A/B is a C-kinesin, containing the minus-end-directed motor domain in the C-terminus. C-kinesins, together with cytoplasmic dynein, are involved in retrograde transport. For example, KIFC2 has been reported to retrogradely transport multivesicular body-like organelles toward the cell body (Saito *et al.*, 1997). In a more recent phylogenetic study, more types of kinesins were identified from previously uncharacterized eukaryotes, leading to the classification of 17 families in total (Wickstead *et al.*, 2010).

Detailed structural analyses of the kinesin motor domain at the atomic level have revealed that the kinesin motor domain has somewhat diverged and evolved in the course of molecular phylogeny, to give rise to new functions other than as a conventional plus-end-directed dimeric microtubule motor. For example, the monomeric kinesin-3 motor KIF1A has an extended Lysine-rich loop called 'K-loop' to gain the electrostatic interaction with microtubules that significantly augment the processivity of motility (Kikkawa *et al.*, 2001; Okada and

Figure 2 Diversity among KIFs. (a) Structure of KIFs. Orange boxes, kinesin motor domains. Reproduced from Miki, H., Okada, Y., Hirokawa, N., 2005. Analysis of the kinesin superfamily: Insights into structure and function. *Trends in Cell Biology* 15, 467–476. (b) Phylogenetic tree of KIFs. Reproduced with permission from Hirokawa, N., Niwa, S., Tanaka, Y., 2010. Molecular motors in neurons: Transport mechanisms and roles in brain function, development, and disease. *Neuron* 68, 610–638.

Hirokawa, 1999). In the case of the depolymerizing kinesin-13 motor KIF2A/B/C, the extended loop 2 is responsible for a depolymerizing activity (Ogawa *et al.*, 2004; Shipley *et al.*, 2004). The retrograde kinesin-14 motors (KIFCs) including Ncd have a specific C-terminal segment which appeared to be crucial for retrograde motility (Heuston *et al.*, 2010; Szczesna and Kasprzak, 2012). Thus, the vast differences in the functions of kinesins are partly due to the diversity of the pleiotropic domain structures in the motor domains.

Motor–Cargo Relationship and Pathophysiological Relevance

In this section, we describe some key examples of the roles of KIFs in important aspects of human diseases, development, and brain functions that have been discovered via molecular genetics and molecular and cellular biology studies.

Axonal Transport Abnormalities Responsible for Neurodegeneration and Common Neurological Diseases

Axonal transport is thought to be affected by several pathological signal transduction cascades, revealing overt symptoms of neuropathies (Holzbaur and Scherer, 2011). As summarized in Figure 3, the major kinesins responsible for axonal transport are kinesin-1 (KIF5A, 5B, and 5C) and kinesin-3 (KIF1A, 1Ba/β, 1C, 13A, 13B, 14, 16A, 16B, and 28). Kinesin-1 transports mitochondria, lysosomes, endosomes, and amyloid precursor protein (APP). APP is responsible for generating beta-amyloid in the brain of patients with Alzheimer disease (Selkoe, 2001), but the detailed mechanistic link between deficiencies in axonal transport and beta-amyloid accumulation and neurodegeneration in Alzheimer disease remains controversial (Lazarov *et al.*, 2005).

The kinesin-3 motors KIF1A and 1Bβ synergistically transport synaptic vesicle precursors (SVPs) containing synaptophysin, synaptotagmin, and Rab3 (Okada *et al.*, 1995; Zhao *et al.*, 2001), which are functional homologs of the *Caenorhabditis elegans* protein Unc-104 (Hall and Hedgecock, 1991). This cargo–motor association is precisely regulated by the Rab3 GTPase cycle, in which Rab3-GTP but not Rab3-GDP can bind to the KIF adaptor protein DENN/MADD. As a result, only SVPs carrying the GTP-bound form of Rab3 can move forward (Niwa *et al.*, 2008). Hippocampal KIF1A is transcriptionally upregulated by environmental stimuli downstream of brain-derived neurotrophic factor (BDNF) signaling, potentially facilitating learning and memory (Kondo *et al.*, 2012). Heterozygous KIF1B-knockout animals suffer from peripheral neuropathy, and one human pedigree of Charcot-Marie-Tooth disease type 2A1 was reported to carry a loss-of-function point mutation in the KIF1B motor domain (Zhao *et al.*, 2001). These phenotypes suggest that the gene dosage of these kinesin-3 motors could strongly affect the viability and performance of neurons.

Dendritic transport of essential molecules such as neurotransmitter receptors

Some kinesins are involved in the trafficking of neurotransmitter receptors in dendrites, thereby modulating the

sensitivity of neurons to neurotransmitters. The kinesin-2 motor KIF17 transports the glutamate receptor NR2B and contributes to learning and memory by generating a self-activation loop via cAMP response element-binding protein (CREB) phosphorylation (Yin *et al.*, 2011, 2012; Wong *et al.*, 2002; Setou *et al.*, 2000; Guillaud *et al.*, 2003, 2008). The kinesin-3 motor KIF13A transports the serotonin type 1A receptor and controls anxiety (Zhou *et al.*, 2013). The kinesin-1 motor KIF5A interacts with GABARAP to control the surface transport of the GABA_AR, which inhibits the occurrence of epilepsy (Nakajima *et al.*, 2012). Kinesin-3 motors KIF1A, KIF13A, and KIF13B are suggested to carry dendritic vesicles in a unique ‘split kinesin’ assay (Jenkins *et al.*, 2012). Kinesin-1 motor KIF5A/B/C interacts with a huge ribonucleoprotein (RNP) complex and carries mRNA into dendrites (Kanai *et al.*, 2004). These data strongly suggest that kinesins regulate brain function.

Ciliogenesis and Left–Right Determination

Cilia and flagella are unique cellular protrusions that principally function in fluid flow generation and signal transduction. The heterotrimeric kinesin-2 complex KIF3A/KIF3B/KAP3 performs an essential role in ciliogenesis by transporting structural components to the tips of cilia, a process defined as intraflagellar transport (IFT) (Rosenbaum and Witman, 2002; Nonaka *et al.*, 1998). Mouse mutants lacking kinesin-2 or IFT components display disorganized left–right determination of the internal organs (Nonaka *et al.*, 1998; Marszalek *et al.*, 1999; Takeda *et al.*, 1999), accompanied in part by other signs of ciliopathy, such as polycystic kidneys (Lin *et al.*, 2003). Ciliogenesis in the ventral node, an embryonic organ, is a key element of this phenomenon. The ventral node is a transient triangular concave structure on the ventral midline surface of the embryo at the early somite stage. Interestingly, monocilia on the ventral node rapidly rotate clockwise around a posteriorly-tilted axis, generating leftward surface fluid flow (nodal flow) (Nonaka *et al.*, 1998). Extracellular vesicles called nodal vesicular parcels (NVPs) were found to be secreted from cell surface protrusions, transferred to the left, and trapped at the left periphery of the node, where they deposit their contents (Tanaka *et al.*, 2005). This leftward flow may induce effects such as left-specific calcium elevation and expression of left-specific genes, which are the bases of the asymmetrical development of the internal organs (Figure 4).

Conversely, KIF19A, another ciliary kinesin-8 motor, depolymerizes microtubules and is essential for decreasing ciliary length (Niwa *et al.*, 2012). KIF19A-knockout mice suffered from hydrocephalus and female infertility caused by abnormally elongated cilia. Thus, the KIF3 complex and KIF19A may synergistically regulate the ciliary length within a proper range.

Depolymerizing Kinesins and Brain Wiring

The kinesin-13 motors KIF2A/2B/2C display microtubule depolymerizing activity. KIF2A-knockout mice display impaired brain wiring and layer formation defects in the developing brain. Primary cultured neurons exhibit abnormally elongated axon collaterals and defects in migration. This abnormality was proposed to be due to defects in the retraction of

Figure 3 Kinesins in neurons. Various KIFs transport membranous organelles anterogradely in axons and dendrites, whereas cytoplasmic dynein 1 and KIFC2 transport cargos retrogradely. In neuronal cilia, anterograde transport is performed by KIF3 and KIF17, whereas retrograde transport is performed by cytoplasmic dynein 2. In short-range transport, such as transport within pre- and postsynapses and growth cone filopodia, the myosin family of proteins functions as the molecular motors. Reproduced with permission from Hirokawa, N., Niwa, S., Tanaka, Y., 2010. Molecular motors in neurons: Transport mechanisms and roles in brain function, development, and disease. *Neuron* 68, 610–638.

unnecessary collateral branches because of the loss of microtubule depolymerizing activity, which could be regulated by phosphoinositide signaling (Homma *et al.*, 2003; Noda *et al.*, 2012). KIF2C (mitotic centromere-associated protein, or

MCAK) is an Aurora kinase-regulated kinesin essential for the proper function of the mitotic apparatus. KIF2C is especially critical for kinetochore-microtubule attachments, cooperating with KIF18B in this process (Tanenbaum *et al.*, 2011).

Figure 4 Kinesin-2-dependent ciliogenesis is essential for left–right body patterning: the initial symmetry-breaking process in vertebrates. (a) Scanning electron micrographs of ventral nodes of wild-type mouse embryos in the ventral view. Arrows, monocilia. Bars, 5 μm . Upper, anterior (A); lower, posterior (P); left of the figure, right (R); right of the figure, left (L) in (a)–(c). (b) Readouts of nodal flow. According to the direction of the nodal flow, the downstream side (left half) of the floor plate expresses *Lefty1*, and the left lateral plate mesoderm expresses *Nodal*, *Lefty2*, and *Pitx2*, possibly via Ca²⁺ elevation and nodal activation at the left periphery of the node. (c and d) Generation of leftward flow by tilted cilia, represented by ventral (c, left) and lateral (c, right; d) views of the node. Due to the expression of planar cell polarity (PCP) genes in the respective anterior and posterior poles of the cells (red, blue, and green lines in the inset of c), the cilia are positioned on the posterior ends of the node cells, resulting in posterior tilting of the clockwise-rotating axes. Accordingly, shear resistance on the surface influences the left-to-right cilia sweep more so than the right-to-left sweep, generating net leftward flow of the extracellular fluids. V, ventral; D, dorsal. (e) NVP hypothesis of signal propagation in the node. FGF signaling in cilia may activate sonic hedgehog (SHH) and retinoic acid (RA) signaling, inducing the release of NVPs from the cell surface with the help of filopodia-like cellular protrusions. NVPs are transported to the left via nodal flow and elevate intracellular Ca²⁺ on the left margin of the node. Reproduced with permission from Hirokawa, N., Tanaka, Y., Okada, Y., 2012. Cilia, KIF3 molecular motor and nodal flow. *Current Opinion in Cell Biology* 24, 31–39.

Kinesins and Cancer

There are some KIFs being largely involved in cell division rather than intracellular transport. For example, KIF11 and KIF15 play roles in generating and maintaining a bipolar spindle, CENPE in chromosome congression, kinesin-4 and kinesin-8 motors in microtubule regulation, and kinesin-6 motors in the central spindle and cytokinesis (Rath and Kozielski, 2012). These mitotic kinesins (kinesin spindle proteins; KSPs; Figure 5) have been considered as major targets for anticancer drugs because cancer cells possess infinite proliferative capacity. Monastrol has been developed as a prototype drug that specifically inhibits a kinesin-5 motor (KIF11, or Eg5) that is essential for spindle bipolarity (Mayer *et al.*, 1999).

Conversely, neuron-specific conditional knockout of the kinesin-2 component KAP3 leads to the formation of brain tumors (Teng *et al.*, 2005). This result was proposed to be due to the cytoplasmic role of kinesin-2 in transporting N-cadherin and β -catenin, which negatively regulates Wnt signaling and augments cell adhesion. Kinesin-2 is also responsible for cilogenesis, which serves for hedgehog signaling (Nonaka *et al.*, 1998; Han *et al.*, 2008). Thus, the kinesin-2 complex is regarded as a tumor suppressor motor via the downregulation of oncogenic signal transduction cascades.

Kinesins as Components of Signal Transduction

Other kinesins serve as components of signal transduction by simply transporting signaling molecules or modulating protein-protein interactions. As an example of the former, the kinesin-3 motor KIF16B acts in concert with the Rab14-GTP adaptor to transport fibroblast growth factor (FGF) receptor 2 through the Golgi-to-endosome pathway, and KIF16B is essential for early embryonic FGF signaling in the differentiation of the hypoblast and epiblast (Ueno *et al.*, 2011). This activity may partially oppose the activity of KIF13B in facilitating caveolin-mediated endocytosis, which is involved in cholesterol metabolism in the adult liver (Kanai *et al.*, 2014).

As an example of protein-protein interactions, the kinesin-11 protein KIF26A lacks motor activity, negatively regulates BDNF-Ret signaling by competitively inhibiting Grb2-SHC binding and is responsible for megacolon (Zhou *et al.*, 2009). Another example of such a nonmotor microtubule-associated adaptor in signal transduction is the *Drosophila* kinesin-11 protein Costal2 (Cos2), which is an essential component of the hedgehog (Hh) signaling cascade that interacts with cubitus interruptus (Ci) and suppressor of fused [Su(fu)] (Sisson *et al.*, 1997; Robbins *et al.*, 1997). However, in mammalian cells, this function in Hh signaling may be substituted by ciliary components, and thus, the precise mammalian homologue of Cos2 has yet to be identified.

Some kinesins function in nuclear signaling in addition to their roles in cytoplasmic transport. The kinesin-4 motor KIF4A binds to and suppress the activity of the enzyme poly(ADP-ribose) polymerase 1 (PARP-1) in the nucleus. This function of KIF4A is responsible for activity-dependent neuronal survival in the developing brain (Midorikawa *et al.*, 2006). KIF17b interacts with a transcriptional coactivator in male germ cells and participates in transcriptional regulation (Kotaja *et al.*, 2005).

These are only a few examples of the multimodal interactions between kinesins and their binding partners and cargos. Future studies will continue to reveal additional surprises regarding the functional relevance of KIFs.

Regulation and Synergy of Kinesins

How are kinesins regulated? This question is essential for incorporating kinesin function into broader aspects of biology, but our understanding of this topic remains limited. However, the following studies described are some examples of such studies that have examined this topic.

Regulation of the Expression Levels of Kinesins

Haploinsufficiency of the *Kif1b* gene can lead to peripheral neuropathy due to a reduction in the levels of the KIF1B β protein (Zhao *et al.*, 2001), demonstrating that changes in the gene dosage of KIFs may be reflected by altered protein expression levels and rates of cargo trafficking. Point mutations in human *KIF* that cause haploinsufficiency are harmful to neurons (Hirokawa *et al.*, 2010; Tanaka and Hirokawa, 2002). Significant KIF mutations found in human neuropathies include the following examples. Knockout of murine *Kif5a* or mutation of the human homolog results in neuronal loss and SPG10-mediated spastic paraplegia (Reid *et al.*, 2002). Knockout of murine *Kif1b* or mutation of human *Kif1b* results in neuronal dysfunction and is responsible for Charcot-Marie-Tooth disease type 2A1 (Zhao *et al.*, 2001) and multiple sclerosis (Aulchenko *et al.*, 2008). *KIF21A* mutation in humans results in atrophy of extraocular muscles and CFEOM1 (Yamada *et al.*, 2003). Thus, pharmacologically augmenting the gene dosage or the residual motor activity of the healthy allele may represent a valuable therapy for these chronic neuropathies.

In contrast, some KIFs that are essential for higher brain functions are known to be upregulated by environmental stimuli. Transcription of the murine SVP transporter *Kif1a* is enhanced by BDNF signaling induced by living in enriched environments with toys in the mouse cage (Kondo *et al.*, 2012). The *Kif17* gene, which encodes a glutamate receptor transporter, is also transcriptionally activated by neuronal stimulation via phosphorylated CREB (Yin *et al.*, 2011; Wong *et al.*, 2002). It has been also known that some mitotic kinesins are transcriptionally regulated over the cell cycle (Verhey and Hammond, 2009). Examples of these types of transcriptional regulation of KIFs corresponding to physiological or pathological changes will be further elucidated by translational studies.

Regulation of Kinesin by Signal Transduction

The function of kinesins can be significantly regulated by global and local stimuli. In this section, we will describe several mechanisms of kinesin regulation (Figure 6).

Kinesins are phosphorylated and dephosphorylated by many kinases and phosphatases in signal transduction cascades, and these events alter their mechano-chemical ATPase activity or cargo-binding capacity. For example, kinesin-1

(a)

Figure 6 Regulation of kinesins. (a) KIF17 releases NMDA-receptor-2B-containing vesicles when phosphorylated by CaMKII, the activity of which is high near postsynapses. (b) KIF1A or KIF1B β recognizes GTP-Rab3 via DENN/MADD and transports Rab3-carrying synaptic vesicle precursors. Rab3 then cycles to the GDP-bound form, most likely via the action of Rab3 GAP at axon terminals, and is released from the motor. (c) A schematic illustrating high Ca^{2+} modifying the EF hand motifs of Miro to inhibit kinesin motor activity. In this model, KIF5 is constitutively localized to mitochondria. (d) A schematic illustrating the release of mitochondria from KIF5 via Ca^{2+} . Reproduced with permission from Hirokawa, N., Niwa, S., Tanaka, Y., 2010. Molecular motors in neurons: Transport mechanisms and roles in brain function, development, and disease. *Neuron* 68, 610–638.

activity is negatively modulated by JNK phosphorylation and this phosphorylation is possibly involved in the pathogenesis of Huntington's disease (Morfini *et al.*, 2009; DeBerg *et al.*, 2013). The cargo-binding domain of the kinesin-2 motor KIF17 is phosphorylated by CaM kinase II (CaMKII). This induces the release of NR2B-containing cargoes, which may be essential for dynamic changes in the cargo-motor-binding cycle, such as the efficient release of cargoes at nerve endings (Yin *et al.*, 2012; Guillaud *et al.*, 2008). The PARP1 binding capacity of KIF4A can also be regulated via phosphorylation by CaM kinase to function in cell survival signaling (Midorikawa *et al.*, 2006). Via these phosphorylation events, kinesins can respond to environmental stimuli and alter their activity to globally modulate cellular activities.

Rab GTPases have been found to be adaptors of kinesin-3 motors (Rab3 for KIF1A/1B β and Rab14 for KIF16B), and the nucleotide cycle of Rabs dramatically modulates the motor-cargo-binding capacity of kinesins (Niwa *et al.*, 2008; Ueno *et al.*, 2011). TrkB receptor is transported by kinesin-1 by the help of the Slp1/Rab27B/CRMP-2 complex (Arimura *et al.*, 2009). Because only the cargos carrying GTP-bound Rabs can associate with the motors, cellular signaling processes that activate Rab GTP exchange factors (GEFs) or GTPase-activating proteins (GAPs) could turn on or turn off axonal transport switches, respectively, both locally and globally.

The regulation of mitochondrial transport has been intensely studied. Calcium entry at synapses could halt the motility of nearby mitochondria, essentially recruiting these mitochondria to active synaptic regions that may require

additional energy. Multiple models have been proposed for the mechanism of calcium-mediated regulation of the interaction between the Milton (Trak1/2)/Miro/syntaxin adaptors, mitochondria, and kinesin-1 motors (Chen and Sheng, 2013; Macaskill *et al.*, 2009; Wang and Schwarz, 2009).

Autonomous Regulation of Kinesin Motility

In parallel to the signal-mediated mechanisms described above, autonomous regulation of motor function has been proposed at the single-molecule level (Verhey *et al.*, 2011). When GFP-tagged full-length kinesins are transfected into neurons, the GFP signal remains in the cell body. However, constructs containing only the motor domains, in most cases, translocate to the plus ends of microtubules and accumulate at the cell periphery or nerve endings. This phenomenon could be explained by the existence of an intramolecular interaction, in which the cargo-binding domain inhibits the motor domain when no cargo is present. This mechanism of self-inhibition is considered to be essential for the efficient recruitment of kinesin motors to microtubules upon cargo binding.

The relationship between kinesin motors with opposing directionalities is also an interesting issue. A 'tug-of-war' mechanism is the simplest model to explain the sudden directional changes in axonally transported organelles, which are likely simultaneously bound to multiple motors with different directionalities. Under this circumstance, what is the status of

the motor with the directionality opposite to the direction of movement? Is it inactivated, more weakly associated with the cargo, dragged along, or generating a normal force that is neutralized by the force of motors moving in the opposite direction? To date, no definitive answer to this question has been found, and multiple models could function in parallel. In the case of the transport of vesicles carrying BDNF, IGF-1/Akt-mediated phosphorylation of huntingtin augments the association of kinesin-1 with the cargo, such that anterograde transport is dominant (Humbert *et al.*, 2002). This finding suggests that receptor tyrosine kinase signaling could affect the directionality of motility by altering the balance in the accessibility of opposing motors. In the case of fungal hyphae, kinesin-3 puncta were detected on an early endosome before a switch in direction (Bielska *et al.*, 2014). However, in the case of *Drosophila* axons, eliminating the expression of a single motor (a kinesin or dynein) was sufficient to halt bi-directional transport (Martin *et al.*, 1999). This result has been largely explained by a model in which the existence of an opposing force increases motor processivity. Alternatively, the status of the local microtubule could be altered by motor binding, but changes in signal transduction or impairments of the transport of opposing motors downstream of motor loss could also be possible.

Regulation of Cargo Destinations

In some cases, the destination of intracellularly transported materials can be precisely regulated by cell polarity. This phenomenon, referred to as 'polarized sorting,' has been intensely studied, particularly in the case of kinesin-1 with respect to the axo-dendritic polarity of neurons.

First, a truncated motor containing only the KIF5 motor domain displayed a preference for axons based on their specific binding preference for GTP-tubulin, which is enriched in axons (Nakata *et al.*, 2011). In fact, a recent cryo-EM study revealed a structural difference between GTP-tubulin and GDP-tubulin and suggested structural cues for the preferential binding of KIF5 to axonal microtubules (Yajima *et al.*, 2012).

On other hand, when the kinesin attaches to dendritic cargos, such as the AMPA receptor subunit GluR2 and the EphB2 receptor, the adaptor GRIP1 directs the kinesin to the somatodendritic pathway (Misra and Ziff, 2005; Hoogenraad *et al.*, 2005; Setou *et al.*, 2002). Conversely, association of the stress protein Hsc70 with kinesin-1 is involved in determining the mode between fast and slow axonal transport (Terada *et al.*, 2010). As another factor regulating the kinesin-1 destination, two different isoforms of TRAK family adaptor proteins differentially regulates the mitochondrial transport into axons and dendrites (van Spronsen *et al.*, 2013). TRAK1 binds to both kinesin-1 and dynein/dynactin and required for axonal transport and axonal outgrowth. However, TRAK2 interferes kinesin-1 binding and predominantly localizes to dendrites to serve for dendritic development.

Posttranslational modifications of C-terminal of tubulin is also essential for kinesin activities (Janke and Kneussel, 2010). Kinesin-1 motility on neuronal β -tubulin (TUBB3) is increased by polyglutamylation and robust kinesin-2 motility requires

detyrosination of α -tubulin (Sirajuddin *et al.*, 2014). Microtubule depolymerization activity of kinesin-13 is regulated by the cytosolic carboxypeptidase CCP-6, which promotes $\Delta 2$ modification of α -tubulin and serves for axon regeneration (Ghosh-Roy *et al.*, 2012).

Furthermore, the microtubule-associated proteins (MAPs), such as MAP2 and tau, are important structural factors that stabilize and bundle the microtubules. They generally give competitive or steric inhibition on kinesin motility (Hagiwara *et al.*, 1994; Dixit *et al.*, 2008; Ebner *et al.*, 1998), which would be another essential factor regulating the axonal transport.

Thus, kinesins may find their destination using multimodal cues, including the identities of their tracks, associated proteins, and cargos.

Concluding Remarks

As has been briefly explored in this article, kinesin molecular motors have been classified into a new category of functional proteins in the past few decades based on investigations using multidisciplinary approaches, including biophysics, biochemistry, molecular and cellular biology, electrophysiology, molecular genetics, and behavioral sciences. Due to the vast mechanochemical properties of their motor domains and due to evolutionary gene shuffling, resulting in the generation of multiple protein-protein interaction domains, kinesins are now regarded as one of the most essential and exquisite motors within living cells. Not only are kinesins regulated by signal transduction cascades, but they also modulate multiple signal transduction pathways by transporting or associating with signaling molecules. Through these mechanisms, kinesins are responsible for multiple human diseases, including cancer, metabolic diseases, neuropathies, and epilepsies, as well as malformations during development and deficits in higher brain function in adults. Thus, kinesin biology provides enormous conceptual advances to various biological concepts and represents a growing field within molecular and cellular biology.

Glossary

Axoneme A microtubule-based structure found in cilia and flagella. It is composed of nine outer doublets of microtubules (MT) arranged in a ring around two central MT singlets. Inner- and outer-arm dyneins drive bending of the axoneme for cell motility.

Cilia and flagella Cellular organelles composed of >400 proteins. Motile cilia generate bending motion driven by axonemal dyneins. Eukaryotic flagella are almost identical to motile cilia and these two terms are exchangeably referred.

Dynactin A protein complex known to associate with the dynein motor. Dynactin increases the processivity of the dynein motor and controls the localization of dynein in the cell.

Dynein A cytoskeletal motor protein that participates in minus-end-directed transport on MTs by coupling adenosine triphosphate (ATP) hydrolysis to mechanical

work. Dyneins are responsible for trafficking of vesicles and organelles, controlling mitotic spindle orientation, driving retrograde axonal transport, and retrograde intraflagellar transport.

Intraflagellar transport The bidirectional trafficking of proteins from the base of a cilium or flagellum to its distal end and back. This process is important in assembly and maintenance of cilia and flagella.

Mechanochemical cycle The cycle of events during which a molecular motor converts chemical energy, usually in the form of ATP, into mechanical work.

Microtubule A tubular, filamentous cytoskeletal structure assembled of 13 linear protofilaments made of polymerized tubulin. Microtubules provide the substrate for dynein motors.

Power stroke The force generating step in the mechanochemical cycle of a molecular motor.

Introduction

Eukaryotic cells are presented with the problems of intracellular organization, coordination, and locomotion, and use adenosine triphosphate (ATP)-driven molecular motors to overcome these challenges. Dyneins are processive, minus-end-directed microtubule (MT) motors that are involved in essential cellular processes, including axonal transport, mitotic spindle formation, and intraflagellar transport (IFT). Dyneins are evolutionarily distinct from the two other families of cytoskeletal motors, myosins and kinesins, and are organized into two classes: axonemal and cytoplasmic. Cytoplasmic dyneins are responsible for much of the minus-end-directed transport of cargoes both within the cell body and in cilia. Axonemal dyneins play a major role in the bending of axonemes that drive ciliary motility. In this article, we discuss the structure, function, and biophysical mechanics of dynein motors.

Architecture of Dyneins

The dynein holoenzyme is composed of 1–3 dynein heavy chains (DHCs), which contain the necessary components for ATP hydrolysis and MT binding, bound to intermediate (IC), light-intermediate (LIC), and light (LC) chains. ICs, LICs, and LCs are responsible for regulating the motility of the HC and recruiting cargo. Each dynein holoenzyme contains two HCs, two ICs, two LICs, and a variable number of LCs (Vallee *et al.*, 2004). Three types of LCs, known as TCTEX, LC8, and Roadblock, have been identified (Roberts *et al.*, 2013). The dynein holoenzyme can be thought of as a modular structure; a

relatively small selection of HCs is repurposed through the binding of a variety of ICs, LICs, and LCs to accomplish a broad array of cellular tasks. Herein we discuss the structure of the DHC and the insights it provides on dynein function.

DHC

Genes which encode DHCs can be sorted into three classes: cytoplasmic, outer-arm, and inner-arm dyneins.

Cytoplasmic DHCs

Cytoplasmic dynein 1 (also known as DYNC1) is the dynein complex that mediates nearly all minus-end-directed transport in eukaryotic cells. Cytoplasmic dynein 2 (DYNC2, referred to here as IFT dynein) has a strong sequence identity to DYNC1, and is responsible for mediating retrograde IFT. Both IFT dynein and cytoplasmic dynein complexes are composed of a homodimer of the respective HCs (Perrone *et al.*, 2003). The cytoplasmic dynein HC is composed of an N-terminal tail domain, a pseudohexameric AAA+ ATPase domain, and a stalk domain (Figure 1). The tail domain is involved in dimerization of the dynein HCs and recruitment of ICs, LICs, and LCs, and contacts the AAA+ domains through a linker region (Carter *et al.*, 2011; Kon *et al.*, 2011; Schmidt *et al.*, 2012; Tynan *et al.*, 2000). The AAA+ ATPase domains (numbered AAA1–AAA6) are responsible for binding and hydrolyzing ATP to power motility. The stalk region emerges from the motor domain at AAA4 as a 15 nm antiparallel coiled-coil with a globular MT-binding domain (MTBD) at its distal end (Kon *et al.*, 2011).

Figure 1 Architecture of the cytoplasmic DHC: the N-terminal tail domain (lavender) is involved in dimerization, the recruitment of ICs, LICs, and adaptor proteins. The linker region (magenta) is docked on the face of the AAA + ring domain at the AAA1 site (dark blue) and the AAA4 site (yellow). The AAA + modules are arranged from AAA1 to AAA6 in a clockwise fashion around the ring. Between AAA4 and AAA5, a ~15 nm coiled-coil stalk emerges with a globular microtubule-binding domain (MTBD) at its distal end. AAA5 contains a short coiled-coil protrusion known as a strut or buttress. The image is courtesy of David S. Goodsell and the RCSB PDB and is available under a CC-BY-3.0 license (<http://creativecommons.org/licenses/by/3.0/us/>).

The AAA + ring domains are part of the ASCE (additional strand catalytic E) superfamily, which contains a diverse array of proteins, including those involved in protein quality control and genome replication (Erzberger and Berger, 2006). The AAA + fold is derived from the core, ancestral ASCE α fold with a C-terminal α -helical domain (Erzberger and Berger, 2006). These two subdomains, often called the large and small subdomains, contain a flexible hinge region between them which allows a rigid-body motion between the large and small domains (Glynn *et al.*, 2009). Biochemical and structural studies suggest that this rigid-body motion communicates nucleotide-dependent conformational changes between AAA + domains (Carter *et al.*, 2011; Glynn *et al.*, 2012; Stinson *et al.*, 2013).

AAA + domains assemble as an asymmetric hexameric ring structure (Erzberger and Berger, 2006). However, dynein is one of two proteins whose AAA + domains are contained within a single polypeptide chain and the sequence and structure of each AAA + domain is unique (Neuwald *et al.*, 1999). The

canonical AAA + fold contains several motifs associated with nucleotide-triphosphate binding, including sensor-I, sensor-II, arginine finger, Walker A, and Walker B motifs (Figure 2). Only AAA1–4 have conserved Walker A and B motifs for catalytic activity. Of these, only AAA1, AAA3, and AAA4 have meaningful ATPase activities (Cho *et al.*, 2008; Kon *et al.*, 2004). Although AAA2 lacks the sensor-II motif and the catalytic glutamate residue of the Walker B motif, structural studies have consistently found electron density from nucleotide binding in the AAA2 pocket (Kon *et al.*, 2012; Schmidt *et al.*, 2012). This evidence suggests that the nucleotide-binding activity of AAA2 serves a structural role. AAA5 and AAA6 have lost their Walker A and B motifs and fail to binding nucleotide in crystallographic studies (Kon *et al.*, 2012; Neuwald *et al.*, 1999; Schmidt *et al.*, 2012).

The stalk domain is an antiparallel coiled-coil that emerges from and returns to the α -helical domain of AAA4 (Kon *et al.*, 2011). The stalk region is a unique feature of dynein; kinesins and myosins have globular head domains that both hydrolyze ATP and bind and release their cytoskeletal track (Kull *et al.*, 1996; Rayment *et al.*, 1993; Woehlke *et al.*, 1997). The coiled-coil stalk is kinked by two highly conserved proline residues near the MTBD (Carter *et al.*, 2008). These proline residues are thought to disturb the heptad-repeat pattern and packing of hydrophobic residues of the coiled-coil (Carter *et al.*, 2008; Nishikawa *et al.*, 2014). The MTBD is composed of a bundle of six α -helices (Carter *et al.*, 2008). Helices H1, H3, and H6 are enriched with positively charged residues and forms the MT-binding interface (Carter *et al.*, 2008; Koonce and Tikhonenko, 2000). Altering the registry of the coiled-coil stalk causes the MTBD to adopt a high-affinity (α) or low-affinity ($\pm\beta$) conformation (Gibbons *et al.*, 2005; Kon *et al.*, 2009). The α conformation of the MTBD is hallmarked by basic residues forming salt bridges with glutamate residues on the surface of the tubulin dimer (Redwine *et al.*, 2012). Moreover, these electrostatic interactions are satisfied by intramolecular salt-bridges within the MTBD in the low-affinity conformation (Redwine *et al.*, 2012).

Dynein Motility

Dynein Stepping Is Uncoordinated

Dynein stepping behavior differs significantly from other cytoskeletal motors. Myosin V and kinesin-1 walk hand-over-hand, in which the trailing head releases from the motor's substrate and advances in the forward direction past the leading head (Yildiz *et al.*, 2003, 2004). Unlike these motors, dynein's step size is highly variable, with most steps being 8–16 nm in size toward the MT minus-end, as well as ~20% steps in backward direction (DeWitt *et al.*, 2012; Qiu *et al.*, 2012; Reck-Peterson *et al.*, 2006). Dynein moves processively by uncoordinated stepping of its two heads (DeWitt *et al.*, 2012; Qiu *et al.*, 2012; Reck-Peterson *et al.*, 2006). The tethered excursion mechanism suggested that each head is able to release from MT and move forward while the partner head serves as a tether to prevent dissociation from the track. Although dynein's stepping is uncoordinated under most conditions, the probability of the trailing head taking a step is highly

Figure 2 Details of the crystal structure of cytoplasmic dynein's motor domain. (a) Topology of the AAA+ domains in the cytoplasmic dynein motor domain. The Sensor 1 (green), Walker B (pink), Walker A (orange), and Sensor 2 (red) motifs are shown on the large and small domains of the complete AAA+ domain shown. The arginine finger (blue) of the neighboring large domain interacts with the small domain. (b) Diagram of nucleotide binding to the AAA+ ring of cytoplasmic dynein for non-soaked crystals and crystals soaked in ATP, adenosine diphosphate (ADP), and AMP-PNP. AAA1 (blue), AAA2 (light blue), AAA3 (green), AAA4 (yellow), AAA5 (orange), and AAA6 (red) are shown with nucleotide-binding pockets represented by white ovals. NT indicates the presence of nucleotide in the indicated binding pocket. (c–f) Details of the nucleotide-binding pocket. (c) The binding cleft of AAA1 from the ATP-soaked crystal has an open conformation, with the putative ATP-binding site indicated in gray. (d) The AAA2 subunit binds tightly to ATP (ball-and-stick representation with orange mesh). Magnesium ion density is shown in magenta. (e) The AAA3 subunit from the ADP-soaked crystal is shown bound to an exchangeable ADP molecule (ball-and-stick representation with orange mesh). (f) The AAA4 subunit is bound to ADP in the ADP-soaked crystal structure. The catalytic glutamate residue of the Walker B motif lies at the end of a short α -helical fragment (black arrow). Reprinted by Schmidt, H., Gleave, E.S., Carter, A.P., 2012. Insights into dynein motor domain function from a 3.3-Å crystal structure. *Nature Structural & Molecular Biology* 19, 492–497. © 2012, with permission from Macmillan Publishers Ltd.

dependent on the separation between the leading and trailing heads, suggesting that interhead tension plays an important role in dynein motility (Cleary *et al.*, 2014; DeWitt *et al.*, 2012). Dynein has also been shown to take sideways steps onto neighboring protofilaments of the MT, and walk in a helical path around the MT surface (Can *et al.*, 2014; Reck-Peterson *et al.*, 2006).

The AAA+ Domains Power Dynein Motility

The DHC contains the necessary components for motility, including the AAA+ ring, which contains conserved motifs for ATP binding and hydrolysis. Because ATPase and MTBDs are segregated from each other in dynein, this brings into question how ATP hydrolysis at ATPase domains is coupled to MT release. The ATPase activity of AAA1 is strictly required for motility and loss of ATP hydrolysis at AAA3 resulted in a greatly reduced velocity compared to wild-type dynein (Kon *et al.*, 2004). Abolishing nucleotide binding at AAA2 reduced the velocity, and AAA2 in the nucleotide-bound state can

propagate conformational changes from AAA1 to the other AAA+ domains via rigid-body motion (Roberts *et al.*, 2013). Loss of AAA3 function results in a >10-fold decrease in velocity and a ~2-fold reduction in stall force, whereas mutation of AAA4 doubles the motor's run length (Cho *et al.*, 2008). LIS1, a dynein adaptor protein that binds at the AAA3–AAA4 junction, increases the time that dynein spends strongly bound to the MT in between steps, indicating that these domains participate in communication between AAA1 and the MTBD (Huang *et al.*, 2012). The ATP hydrolysis cycles of AAA1 and AAA3 are uncoordinated and that the post-hydrolysis state of AAA3 site facilitates communication between AAA1 and the MTBD (Bhabha *et al.*, 2014; Dewitt *et al.*, 2015).

Communication of the nucleotide state of AAA1 is propagated by rigid-body motions of the other AAA+ domains (Schmidt *et al.*, 2014). When ATP is bound and hydrolyzed at AAA1, the gap between the AAA1 and AAA2 sites closes. Closure of this site triggers the buttress, a short coiled-coil projection from AAA5, to slide the stalk's coiled-coil helices with respect to each other (Schmidt *et al.*, 2014). This ultimately renders the MTBD in a low-affinity state, allowing the

motor to release from the MT during its stepping cycle (Schmidt *et al.*, 2014).

Force Generation

The force generation cycles of other cytoskeletal motors depend on ATP binding or hydrolysis activity to drive the forward movement by rotating a lever arm-like mechanical element (Vale and Milligan, 2000). Dynein, on the other hand, is thought to operate by a winch mechanism, where the power stroke is used to reduce the distance between dynein and its cargo (Carter *et al.*, 2008; Movassagh *et al.*, 2010; Ueno *et al.*, 2008). The first step of the dynein mechanochemical cycle involves binding of ATP at the AAA1 site, which triggers the release of the MTBD from the MT (Figure 3; Roberts *et al.*, 2013). During ATP hydrolysis at AAA1, the gap between AAA1 and AAA2 closes and forces the linker into a bent conformation (Roberts *et al.*, 2012; Schmidt *et al.*, 2014). After a diffusional search for a new MT-binding site in the minus-end direction, the linker undergoes a second conformational change, known as the power stroke (Figure 3; Roberts *et al.*, 2013). During the power stroke, the linker returns to its original conformation and docks near the AAA5 site (Roberts *et al.*, 2012; Schmidt *et al.*, 2012). Each motor head in the dynein dimer produces half the stall force of the dimer (Belyy *et al.*, 2014). Therefore, dynein motor heads share the load, which can produce motility against high-hindering forces, and

explains how multiple dyneins attached to a single cargo can team together more efficiently (Derr *et al.*, 2012).

Force production of dynein per mechanochemical cycle varies from organism to organism. Optical trap studies showed that the motility of mammalian dynein stalls at resistive forces of ~ 1.1 pN resistive forces (Hendricks *et al.*, 2012; Mallik *et al.*, 2004; McKenney *et al.*, 2010; Rai *et al.*, 2013; Schroeder *et al.*, 2010). In contrast, cytoplasmic dynein from porcine brain and *Saccharomyces cerevisiae* have 3–7 pN stall forces (Belyy *et al.*, 2014; Gennerich *et al.*, 2007; Toba *et al.*, 2006; Walter *et al.*, 2010). Estimates from *in vivo* studies in *Drosophila melanogaster* and *Reticulomyxa* indicate that dynein's stall force is between 2 and 5 pN (Ashkin *et al.*, 1990; Shubeita *et al.*, 2008). Resistive loads increase the frequency of backward stepping and decrease the frequency of forward steps larger than 12 nm (Gennerich *et al.*, 2007). Resisting forces greater than the stall force resulted in plus-end-directed stepping (Gennerich *et al.*, 2007). The rate of backward stepping was independent of ATP concentration, in contrast to the rate of forward stepping under assisting load (Gennerich *et al.*, 2007).

Intramolecular tension plays a role in coordination of the stepping motility of cytoskeletal motors (Guydosh and Block, 2006; Spudich, 2006; Yildiz *et al.*, 2008). A dynein dimer may experience tension when the two motor heads are separated by a large distance. Tension on the linker inhibits ATP-induced release of the motor from the MT, and dynein exhibits partially coordinated stepping at high interhead separations (Cleary *et al.*, 2014; DeWitt *et al.*, 2012). Tension on the linker may

Figure 3 Model for the cytoplasmic dynein mechanochemical cycle and power stroke. The AAA1 ATP-binding pocket is in the apo state and the linker region is in the unprimed conformation at the beginning of the cycle. ATP binding at AAA1 triggers release of the MTBD from the MT. The linker undergoes the priming stroke and adopts a bent conformation, after which the MTBD advances toward the minus-end after a diffusional search for a new binding site. ATP is then hydrolyzed, inorganic phosphate is released, and the linker undergoes the power stroke to pull the bound cargo toward the MT minus-end. Cytoplasmic dynein returns to the beginning of its mechanochemical cycle after the linker returns to the unprimed position and ADP is released.

disrupt contacts between the linker and the AAA+ ring domain, as mutations to the linker-AAA+ ring interface reduce the ATPase activity and the velocity of the motor (Kon *et al.*, 2012; Schmidt *et al.*, 2012).

The Mechanism of Dynein Directionality

The original model for dynein's minus-end directionality came from a cryo-EM study of outer-arm dynein, which posited that movement of the N-terminal tail domain is responsible for minus-end-directed movement (Burgess *et al.*, 2003). It has been proposed that the priming stroke, during which the linker adopts a bent shape across the face of the AAA+ ring, allows the unbound head to push against the MT-bound head (Roberts *et al.*, 2009). However, the force generation occurs in the MT-bound state of the motor, and the priming stroke does not produce substantial amount of work (Belyy *et al.*, 2014). In addition, the reversal of dynein's power stroke by heptad insertions in the coiled-coil stalk did not reverse directionality (Carter *et al.*, 2008). These observations suggested that dynein directionality is determined by an element outside the AAA+ ring and the linker (Carter *et al.*, 2008).

Regulation of Dynein Motility

Because dynein is the only minus-end-directed motor, excluding kinesin-14, many adaptor proteins exist to repurpose the cytoplasmic DHC for different cellular processes. Dynactin, a 1.2 MDa protein complex composed of 11 different proteins, is required for all dynein-mediated processes in all cell types (Schroer, 2004). Most other proteins that regulate dynein motility are used for specific purposes, such as controlling mitotic spindle orientation, recruitment of dynein to the kinetochore, and trafficking organelles and mRNAs (Kardon and Vale, 2009).

Dynactin

Dynactin was initially identified as a factor that promoted trafficking of vesicles mediated by cytoplasmic dynein (Schroer, 2004). Dynactin is composed of the Arp1 rod, which contains Arp1, Arp11, actin, CapZ, p62, p27, and p25, along with p150^{glued}, dynamitin, and p24/p22 (Schroer, 2004). P150^{glued} is the largest component of the dynactin complex, and contains a cytoskeleton-associated protein, glycine-rich (CAP-Gly) domain (Schroer, 2004). The CAP-Gly domain of p150^{glued} has been shown to bind MTs *in vivo* and *in vitro* (Vaughan *et al.*, 2002; Waterman-Storer *et al.*, 1995). It has been proposed that the MTBD present in p150^{glued} acts as an extra tether to the MT (Waterman-Storer *et al.*, 1995).

Features of the dynein-dynactin complex are enhanced processivity and bidirectional motility (King and Schroer, 2000; Ross *et al.*, 2006). *In vitro* reconstitution has shown that dynactin, along with BICD2, is strictly required for robust, processive motion of human cytoplasmic dynein (McKenney *et al.*, 2014; Schlager *et al.*, 2014). Single-molecule fluorescence experiments have confirmed that dynactin increases yeast dynein processivity by ~2-fold. However, deletion of the CAP-

Gly domain of p150^{glued} did not alter the processivity *in vitro* or *in vivo* (Kardon *et al.*, 2009). In contrast, another group found that a removal or mutation of the CAP-Gly domain of p150^{glued} prevented the dynein-dependent translocation of the mitotic spindle and nucleus into the bud neck of *S. cerevisiae* yeast, and decreased the frequency of spindle oscillations (Moore *et al.*, 2009). The mechanistic details of dynactin's effect on dynein processivity remain unknown and highly controversial.

Dynactin also plays a role in recruiting cargo to the cytoplasmic dynein holoenzyme. Dynactin binds EB1 to target dynein to the plus-ends of MTs (Kardon and Vale, 2009). Dynactin's Arp1 also interacts with β III spectrin found on the surface of the Golgi (Kardon and Vale, 2009). P150^{glued} has also been shown to interact with SEC23, to bind vesicles emerging from the endoplasmic reticulum (ER) (Watson *et al.*, 2005). Thus, dynactin not only regulates the dynein HC's motility, but also adapts it for multiple functions within the cell.

Lissencephaly 1 and Nuclear Distribution E

The *LIS1* gene's namesake is a condition known as lissencephaly, which causes the gyri and sulci of the cerebral cortices to take on a smoothed appearance (Dobyns *et al.*, 1993). Lis1 is homologous to the *Aspergillus nidulans* protein NudF (Efimov and Morris, 2000). Loss of NudF function causes nuclear migration defects in this filamentous fungus species (Xiang *et al.*, 1994). Lis1/NudF interacts both physically and genetically with NudE (Efimov and Morris, 2000). Lis1-NudE, and its mammalian homolog LIS1-NudE-like (protein) (NUDEL), have been shown to be instrumental in recruiting dynein to the kinetochore, transport of mRNAs, and positioning of the mitotic spindle (Kardon and Vale, 2009). Moreover, both LIS1 and NUDEL are required for normal transport of organelles in the axons of mammalian neuronal cells (Pandey and Smith, 2011).

Lis1 binds to the AAA3 and AAA4 domains, both of which have been previously implicated in controlling speed and processivity of the motor (Huang *et al.*, 2012). Lis1/LIS1 binding renders dynein in a strongly bound MT state, while disengaging the ATPase activity at AAA1 from MT release (Huang *et al.*, 2012; McKenney *et al.*, 2010).

Functions of Cytoplasmic Dynein *In Vivo*

Transport of Cellular Cargoes

Cytoplasmic dynein can transport a large array of cargoes within a cell, including mitochondria, lysosomes, phagosomes, melanosomes, peroxisomes, vesicles emerging from the ER, lipid droplets, and endosomes (Roberts *et al.*, 2013). In recent years, dynein has been shown to transport more exotic cargo, such as transcription factors and viral particles (Dodding and Way, 2011; Harrell *et al.*, 2004). The cytoplasmic dynein holoenzyme even plays roles in specialized cells, including trafficking of MTs into the immunological synapse of T cells and growth cone of neuronal precursor cells (Combs *et al.*, 2006; Grabham *et al.*, 2007).

mRNA Transport

Bicaudal D (BicD) is a dynein adaptor protein identified in *D. melanogaster* embryos. Mutation of the BicD gene results in a lack of anterior structures in *D. melanogaster*, suggesting this gene's role in developmental patterning (Mohler and Wieschaus, 1986; Steward and Nüsslein-Volhard, 1986). BicD and Egalitarian (Egl) are required for dynein-dependent transport and localization of mRNAs during *D. melanogaster* oogenesis and embryogenesis (Delanoue and Davis, 2005; Mach and Lehmann, 1997; Navarro *et al.*, 2004). Egl binds to mRNA localization elements, in addition to interacting with the cargo-binding domain of BicD (Dienstbier *et al.*, 2009). The localization of an mRNA is dependent of the number of copies of Egl/BicD-bound dynein complexes recruited to the mRNA molecule (Bullock *et al.*, 2006). Outside of mRNA transport, BicD also promotes transport of clathrin-coated vesicles in *D. melanogaster*, and its metazoan homolog BICD-1 is involved in nuclear migration in *Caenorhabditis elegans* (Fridolfsson *et al.*, 2010; Li *et al.*, 2010).

Axonal Transport

Axonal transport describes the phenomenon in which organelles, vesicles, proteins, and other cargoes are transported down the axon of neuronal cells. Kinesin-1 and cytoplasmic dynein are the workhorses of axonal transport machinery, and dysfunction of these motors and their accessory proteins results in neurodevelopmental and neurodegenerative disease (Maday *et al.*, 2014). Anterograde transport describes the trafficking of cargoes from the neuron cell body out to the axon termini, while retrograde transport removes aging proteins and organelles from the axon termini for recycling at the cell body (Maday *et al.*, 2014). Dynein has also been discovered to be involved in the bidirectional transport of late endosomes, lysosomes, neurofilaments, and autophagosomes (Maday *et al.*, 2014). Dynein and dynactin have also been implicated in establishing the uniform polarity of MTs in the axon (Ahmad *et al.*, 1998). Dynein and dynactin also participate in the injury-induced signaling complex that transports transcription factors, such as pSTAT3, from the axon back to nucleus so that the axon can be regenerated (Rishal and Fainzilber, 2014).

Nuclear Migration and Cell Motility

Clues about cytoplasmic dynein's role in nuclear migration first came from the identification of NudE in the filamentous, multinucleated fungi, *A. nidulans*. The LIS1–NUDEL complex is known to couple the migration of the nucleus and centrosome (also known as the MT organization center) in nascent neurons during corticogenesis (Shu *et al.*, 2004; Tanaka *et al.*, 2004; Tsai *et al.*, 2007). LIS1–NUDEL plays a similar role in directed cell movement of fibroblasts (Dujardin *et al.*, 2003; Palazzo *et al.*, 2001). Cytoplasmic dynein maintains the position of the centrosome at the cell centroid during the re-orientation of motile fibroblasts, and inhibition of dynein–dynactin results in reduced cell motility (Dujardin *et al.*, 2003; Gomes *et al.*, 2005). Additionally, cytoplasmic dynein drives nuclear rotation in this cell type (Levy and Holzbaur, 2008).

Mitosis and Spindle Assembly

Cytoplasmic dynein is essential for the morphology and assembly of the mitotic spindle. Studies using *Xenopus laevis* egg extracts revealed that cytoplasmic dynein interacts with nuclear mitotic apparatus (NuMA) to focus the minus-ends of the mitotic spindle poles (Heald *et al.*, 1996; Merdes *et al.*, 1996). Cytoplasmic dynein, dynactin, and NuMA affect spindle morphology by regulating the length of the mitotic spindle and MT depolymerization at the minus-end (Gaetz and Kapoor, 2004). The mechanism of MT organization at the mitotic spindle is unknown, but there is strong evidence to suggest that cytoplasmic dynein plays an important role. Fusion of preassembled mitotic spindles depends on dynein-driven sliding of antiparallel MTs (Gatlin *et al.*, 2009). Dynein also counters the kinesin-5 driven outward sliding of antiparallel MTs to maintain the proper tension and length of the spindle, in addition to driving the MT severance response of the mitotic spindle (Elting *et al.*, 2014; Mitchison *et al.*, 2005; Tanenbaum *et al.*, 2008).

Cytoplasmic dynein is also required for the appropriate segregation of chromosomes during mitosis and spindle assembly checkpoint (SAC) inactivation. Kinetochore-associated dynein has been shown to maintain kinetochore orientation and stabilize kinetochore MTs (Figure 4; Varma *et al.*, 2008; Yang *et al.*, 2007). Cytoplasmic dynein is recruited to the kinetochore by the Rod–Zw10–Zwilch (RZZ) complex, which also serves to recruit mitotic arrest deficient 1 (MAD1), MAD2, and Spindly (Kardon and Vale, 2009). RZZ only interacts with a specific phosphorylated epitope of cytoplasmic dynein, which only occurs before chromosomes are aligned at the metaphase plate (Figure 4; Kardon and Vale, 2009). Once bioriented kinetochore attachment to the mitotic spindle is achieved, dynein transports MAD1, MAD2, and Spindly toward the spindle poles to inactivate the SAC (Figure 4; Howell *et al.*, 2001).

Dynein also helps orient astral MTs on the cell cortex. Ric-8A and Gi α recruit a ternary complex of dynein, LGN, and NuMA to the cell cortex (Woodard *et al.*, 2010), but the spindle position and orientation are regulated by pole-localized polo-like kinase 1 (Plk1) and RanGTP (Kiyomitsu and Cheeseman, 2012). Plk1 negatively regulates cortical dynein positioning by dissociating the dynein–dynactin complex from the LGN–NuMA complex, while the chromosome-derived RanGTP gradient restricts LGN–NuMA binding to lateral cell cortex (Kiyomitsu and Cheeseman, 2012). Dynein's role in asymmetric cell division and stem cell differentiation remains unknown, but Lis1 has been implicated in asymmetric cell division of *D. melanogaster* neuroblasts (Siller and Doe, 2008).

IFT Dynein

IFT is crucial for the maintenance of cilia and flagella and facilitates the turnover of ciliary and flagellar proteins (Roberts *et al.*, 2013). IFT machinery traffics cargo from the tip to the base of the cilia in repetitive multiprotein complexes, known as 'IFT trains' (Roberts *et al.*, 2013). Retrograde transport of IFT trains is driven by IFT dynein (Pazour *et al.*, 1998, 1999; Porter *et al.*, 1999), which has strong sequence similarity to that of cytoplasmic dynein (Gibbons *et al.*, 1994). IFT trains are

Figure 4 Function of cytoplasmic dynein and its adaptors at the mitotic kinetochore. (a) Geometry of the mitotic spindle showing how dynein interacts with the kinetochore when the chromosome is unattached to any MTs, attached to one MT in an end-on fashion, and attached to two bioriented MTs. In end-on MT attachment, dynein, bound to LIS1, NUDE/NUDEL, dynactin, and RZZ, exerts tension on a captured astral MT. Dynein traffics SAC proteins away from the kinetochore after bioriented MT attachment is achieved. (b) Schematic of the interactions between dynein, LIS1, NUDE/NUDEL, RZZ, Spindly, and dynactin at the kinetochore. NUDE/NUDEL, RZZ, and SAC proteins directly interact with the kinetochore. Dynein has direct interactions with dynactin, LIS1, RZZ, and NUDE/NUDEL. RZZ only directly interacts with dynein when it is phosphorylated immediately before the alignment of chromosomes at the metaphase plate.

transported by multiple dynein motors (Laib *et al.*, 2009; Shih *et al.*, 2013) at 1–3.5 $\mu\text{m s}^{-1}$ (Signor *et al.*, 1999). IFT dynein also drives whole cell gliding motility in *Chlamydomonas reinhardtii* (Shih *et al.*, 2013). IFT dynein has been shown to have roles outside of IFT, including trafficking signaling proteins involved in vertebrate development. Loss of IFT dynein function at the primary cilium has been associated with disruption of Smo localization and Gli2 trafficking and activation, establishing a link between proper IFT dynein function to Hedgehog-dependent developmental patterning (Kim *et al.*, 2009; May *et al.*, 2005).

(Lawrence *et al.*, 2001) (higher plants have no cytoplasmic dynein, either), *Cryptosporidium*, *Phaeodactylum*, *Caenorhabditis*, *Saccharomyces*, and *Schizosaccharomyces* (they have only cytoplasmic dynein). Interestingly, *Ostreococcus* has axonemal dynein (dynein f) (Wickstead and Gull, 2007), but no cilia. There are variety of motion in cilia from different species and under different conditions – symmetric, asymmetric, and, in multiciliated cells and tissues, metachronal (wavy and sequential). Characterization of axonemal dyneins and their interaction with other components are essential to reveal the mechanism of ciliary motion.

Axonemal Dyneins: Overall Arrangement and Structure

Axonemal dynein is a family of MT-based ATPase motor proteins, which drive the axoneme, a bending cellular appendage in motile cilia and flagella (we use the term cilia in this article) in eukaryotes, from protozoa to vertebrates. Axonemal dynein does not exist in primary cilia. Wide varieties of species have motile cilia in organs such as tracheae, brains, oviducts and sperm, and therefore axonemal dyneins. Examples of species which lack axonemal dynein are higher plant

Molecular Arrangement in the Axoneme

The arrangement of axonemal dyneins in cilia is highly conserved among species – from unicellular algae to human. Motile cilia from most species have a common 9 + 2 axoneme structure, in which nine microtubule doublets (MTD) surround two single MTs. There are also 9 + 0 motile cilia, such as eel sperm (Gibbons *et al.*, 1983, 1985), nodal cilia (Basu and Brueckner, 2008), and centric diatom (*Thalassiosira*) flagella (Armbrust *et al.*, 2004). Exceptionally there are species which have

axonemes with more than nine MTDs, for example, the cecidomyid dipteran *Monarthropalpus flavus* (Lupetti *et al.*, 2005).

Each MTD has 96 nm periodic units. The structure based on cryo-electron tomography of *Chlamydomonas* flagella is shown in Figure 5. Within a periodic unit, there are outer dynein arms (ODA), inner dynein arms (IDA), radial spokes (RS), which connect MTD and central pair singlet MTs (CP), dynein regulatory complexes (DRC), which connect adjacent MTDs, and other components. Both ODA and IDA consist of

Figure 5 3D structure and dynein arrangement in the axoneme. (a) Periodic unit of MTD, out of nine, from *Chlamydomonas* flagella. Red, ODA; Cyan, IDA; Blue, RS; Yellow, IC/LC of dynein f; Green, DRC. The structure is available in the EM Databank as EMD2117 (Bui *et al.*, 2012). (b) Atomic models of cytoplasmic dynein heads (Kon *et al.*, 2012) are fitted to the cryo-ET structure. Cyan, IAD; Red, OAD. (c) Conformational change of axonemal dynein, modeled by fitting the atomic model to cryo-EM structure (Roberts *et al.*, 2012). Modified from Roberts, A.J., Malkova, B., Walker, M.L., *et al.*, 2012. ATP-driven remodeling of the linker domain in the dynein motor. Structure 20, 1670–1680.

components with various sizes: HCs (HC) (400–500 kDa), IC (45–140 kDa), and light chains (LC) (8–28 kDa).

An ODA consists of two or three outer-arm dyneins (OAD), forming bilobed or trilobed structure, and make an array with 24 nm repeat. Unikonts (single flagellum) have two HC in the ODA, while bikonts have three. These OAD are named α , β , and γ . In the two-headed ODA, innermost and outermost dyneins are called the α - and β -families, respectively. In the three-headed ODA, except *Chlamydomonas*, outermost is called γ -dynein. By historical reasons, only in *Chlamydomonas* the innermost dynein is named gamma and the outermost alpha (Figure 5(a)). No homologue of *Chlamydomonas* α -dynein has been found in human by sequence search (Altschul *et al.*, 1990).

There are normally eight inner-arm dyneins (IAD) within one 96 nm unit, longitudinally along MTD. In *Chlamydomonas* flagella, loci of eight major IAD are known: from the proximal end to the distal end, dynein $f\beta$, dynein $f\alpha$, dynein a, dynein b, dynein c, dynein e, dynein g, and dynein d (Bui *et al.*, 2012; Figure 5(a)). Although sequence homology gives us some hints, location of inner dyneins from other organisms is still to be analyzed. In both ODA and IDA, dyneins link two adjacent MTDs. The N-terminal tails are anchored permanently on the A-tubule, while the MTBD interacts with the B-tubule of the adjacent MTD. The N-terminal tail extends from the AAA-ring toward the distal end of the axoneme (plus end of the MTD) (Bui *et al.*, 2008; Figure 5(b)).

Nucleotide-Induced Conformational Change

By fitting atomic models (Kon *et al.*, 2012) to single-particle cryo-EM analysis of IAD dynein c, it was shown that rearrangement of the linker domain takes place during the power stroke of dynein (Roberts *et al.*, 2012). At the post-power stroke conformation solved by crystallography (Kon *et al.*, 2012; Schmidt *et al.*, 2012), the linker spans over AAA4. As proved by single-particle EM (Roberts *et al.*, 2012), the linker changes its conformation and extends over AAA2 and AAA3 (Figure 5(c)). This result was supported by tomography of the axoneme as well (Lin *et al.*, 2014; Ueno *et al.*, 2014). The angle of the stalk extending from the AAA-ring to the B-tubule is, regardless of nucleotide states, tilted toward the proximal end (Movassagh *et al.*, 2010; Ueno *et al.*, 2008), implying the absence of large swing for power stroke (Figure 5(c)). Instead, ~ 8 nm shift of the AAA-ring with respect to the A-tubule was found (Movassagh *et al.*, 2010), suggesting the shift of the head 'pulls' the adjacent B-tubule. However, according to cryo-ET, slight rotation was detected: the angle of the stalk with respect to the B-tubule is $\sim 5^\circ$ shallower in the pre-power-stroke state than in the post-powerstroke state (Lin *et al.*, 2014; Movassagh *et al.*, 2010; Ueno *et al.*, 2014), which may suggest active rotation of axonemal dynein to 'push' the B-tubule.

Diversity of DHC Genes

Although there are two or three OADs and eight IADs in one 96 nm unit, each species has more genes of DHCs. *Chlamydomonas* has 16 DHC genes, while *Tetrahymena* has 25. Based on sequence analysis, they are classified into nine major classes of HC (Morris *et al.*, 2006; Wickstead and Gull, 2007; Wilkes

et al., 2008), seven out of which are axonemal – called outer alpha, outer beta, IAD-1 α , IAD-1 β , IAD-3, IAD-4, and IAD-5 (Morris *et al.*, 2006; Wickstead and Gull, 2007). IAD-1 α and IAD-1 β form a dimer. IAD-3, IAD-4, and IAD-5 are single-headed dyneins.

Products of *Chlamydomonas* IAD genes (DHC1-12) are named, based on biochemical analysis, dyneins a–g. Dynein f (DHC1 and DHC10) is dimeric, corresponding to IAD-1 α and -1 β (Figure 5(a)). There are 10 monomeric IADs. While there are six loci for single-headed IADs in one 96 nm unit, occupied by dyneins a, b, c, e, g, and d (from proximal to distal) (Bui *et al.*, 2008, 2012), other four IADs are called minor dyneins (DHC3, DHC4, DHC11, and DHC12) (Yagi *et al.*, 2009). Dynein d belongs to IAD-4. DHC3 and dynein g (DHC7) belong to IAD-5. All other except DHC12 belong to IAD-3. In *Tetrahymena* DYH1 and 2 are cytoplasmic. DYH3–5 are OAD. DYH 6 and 7 are two-headed IAD. The other 18 DHCs are single headed. Dissimilarly to *Chlamydomonas* and *Tetrahymena*, human has duplication in OAD. β -HC orthologs of human are DNAH11, DNAH17, and DNAH9, while DNAH5 and DNAH8 are γ -HC homologs (Table 1).

The phylogenetic tree of dynein spreads from cytoplasmic dynein (Figure 6(a)). Judging from the dynein family from diverse lineages, a common ancestor of dyneins likely existed before the diversification of eukaryotes and then was lost in some species (Wickstead and Gull, 2012). In the two-headed ODA, α - and β -families are not necessarily monophyletic (Morris *et al.*, 2006; Wickstead and Gull, 2007; Wilkes *et al.*, 2008). In the three-headed ODA, the outermost also belongs to β -family (Sakakibara *et al.*, 1991) and is not classifiable from the central ODAs by phylogenetic analysis (Wickstead and Gull, 2007; Wilkes *et al.*, 2008). It is not clear why and how so many duplications took place, such as in the OAD- β family, IAD-3, and IAD-5 of *Tetrahymena* (Wickstead and Gull, 2007; Wilkes *et al.*, 2008).

Localization and Asymmetry in the Axoneme

One clue to that question is localization of dynein isoforms. In human distribution of OAD, isoforms depends on organs: DNAH5 in the lung, brain, and testis (Olbrich *et al.*, 2002); DNAH9 in respiratory, lung, and sperm (Reed *et al.*, 2000); DNAH8 testis specific (Samant *et al.*, 2002). Uneven distribution can be observed within one cilium. While DNAH5 exists in the entire length of cilia, DNAH9 is localized to the distal part of cilia (Fliegauf *et al.*, 2007; Figure 6(b)).

Localization of dynein species has been studied at the ultrastructural level in *Chlamydomonas*. Electron microscopy of sections of biflagellated *Chlamydomonas* proved that apposed MTDs (we name it MTD1) in two cilia lack ODA (Figure 6(c); Hoops and Witman, 1983). They also reported unusual linkers between this MTD and one adjacent MTD (MTD2) at the proximal area of cilia (Figure 6(c)). After circumferential asymmetry of IAD from bop2 mutant was reported (King *et al.*, 1994), detailed 3D reconstruction from cryo-ET depicted circumferential and longitudinal asymmetry of IAD in wild-type *Chlamydomonas*. Dynein b is missing in MTD1, MTD9, and in the proximal area of all the MTDs (Bui *et al.*, 2009, 2012). Dynein c and f are missing in the entire MTD1 and the proximal area of MTD1, respectively (Bui *et al.*, 2012). Minor dyneins were proved to be localized in the proximal area of *Chlamydomonas* flagella (Yagi *et al.*, 2009; Figure 6(b)), replacing other IADs (Bui *et al.*, 2012). The asymmetry of dynein distribution suggests the sliding force and direction is not homogeneous in the entire cilia and this heterogeneity leads specific waveforms of cilia.

Function of Axonemal Dynein HCs in Cilia

MT sliding caused by dynein is the source of bending (Brokaw, 1989; Satir, 1968; Shingyoji *et al.*, 1977; Summers and

Table 1 16 isoforms of dyneins in *Chlamydomonas*

Protein	Gene	Binding components	Oligomerization	<i>Tetrahymena</i> homologue	Human homologue
OAD α			Trimer	DYH5 (γ)	
OAD β			Trimer	DYH4 (β)	DNAH11, 17, 9
OAD γ			Trimer	DYH3 (α)	DNAH5, 8
Dynein f α	DHC1	IC140, IC138, IC97,	Dimer	DYH6	DYH10
Dynein f β	DHC10	FAP120, Tctex1, Tctex2b, LC7a, LC7b, LC8	Dimer	DYH7	DYH9, 17
Dynein a	DHC6	Actin, p28, RS1	Single headed		
Dynein b	DHC5	Actin, centrin, RS1	Single headed		
Dynein c	DHC9	Actin, p28, RS2	Single headed		
Dynein e	DHC8	Actin, centrin, RS2	Single headed		
Dynein g	DHC7	Actin, centrin, RS3	Single headed		
Dynein d	DHC2	Actin, p28, p38, p44, RS3	Single headed		
Minor IAD	DHC3	Actin, centrin	Single headed		
Minor IAD	DHC4	Actin, centrin	Single headed		
Minor IAD	DHC11	Actin, p28	Single headed		
Minor IAD	DHC12		Single headed		
Cytoplasmic dynein			Homodimer	DYH2	DYNC2H1

Gibbons, 1971). But, the mechanism to integrate the sliding of individual DHCs into bending is unclear. The Switching model (Satir and Matsuoka, 1989; Wais-Steider and Satir, 1979) proposed that dyneins on one side of the axoneme is active and the other side is inactive, depending on the curvature. Recent cryo-ET of sperm flagella supports this model (Lin *et al.*, 2014). A number of theoretical studies were done to formulate force regulation as function of curvature or other geometric parameter of the axoneme to explain bending motion (Brokaw, 2009; Lindemann and Lesich, 2010; Riedel-Kruse *et al.*, 2007; Woolley, 2010). While switching is still a phenomenon to be detected, the mechanism of switching is unknown. It may be caused by regulation by IC/LC and RS/CP (Inoue and Shingyoji, 2007; Lehtreck and Witman, 2007; Lehtreck *et al.*, 2008; Nakano *et al.*, 2003; Porter and Sale, 2000; Smith, 2002), mechano-sensing of DHC or combination of them.

To address these questions, function of dynein is evaluated at multiple scales. Isolated DHC is measured by *in vitro* motility assay. Many dynein species with regulatory proteins are integrated into bending motion in the axoneme and therefore

its waveform, beating frequency, and the velocity of the whole cell are investigated by light microscopy. Between *in vitro* and *in vivo* levels, there is an experiment called sliding disintegration, in which MTDs slide out from enzymatically treated axonemes (Sale *et al.*, 1993; Summers and Gibbons, 1971).

At the level of single HC of axonemal dyneins, it is known that AAA2, 3, and 4 are non-catalytic (Kikushima *et al.*, 2004; Shiroguchi and Toyoshima, 2001). When ATP binds to AAA2–4, crossbridge is formed; when ADP binds, no crossbridge (Shingyoji, 2009; Yoshimura *et al.*, 2007).

Some studies indicate mechano-sensory function of axonemal dyneins. Mechanical stimulation can induce bending in paralyzed flagella (Hayashibe *et al.*, 1997; Inoue and Shingyoji, 2007). Mechanical induction occurs only when ADP binds. Already active dynein does not need ADP-binding (Hayashi and Shingyoji, 2008). Some ODA mutants of *Chlamydomonas* decrease beating under viscous condition (Minoura and Kamiya, 1995), which might be an evidence of mechano-sensing by dynein. Another phenomenon suggesting sensory function was found in cryo-electron tomography of the axoneme in the presence of ATP analog (Movassagh *et al.*,

2010). In the presence of non-hydrolysable nucleotide analog, OADs in the axoneme form nucleotide-bound or apo conformations, making clusters. This experiment indicates cooperativity between OADs on MTD – conformational changes of OADs are not independent of each other. This phenomenon could be explained by mechano-sensing by dyneins.

Distinct Roles of Outer and Inner Dynein Arm HCs

ODA mutants are slow and reduce beat frequency, but swim with the proper waveform (Kamiya and Okamoto, 1985; Mitchell and Rosenbaum, 1985). Also in sea urchin sperm defect of ODA causes decrease of frequency and power (Gibbons and Gibbons, 1973), while IDA-deficient mutant reduces the amplitude of bending motion or totally paralyzed.

Dynein f mutant shows alternation of waveform and less efficient beat (Kamiya *et al.*, 1991). Dynein f *in vitro* is processive, but slow ($1.5\text{--}3.0\ \mu\text{m sec}^{-1}$) (Kotani *et al.*, 2007), compared to other dyneins ($20\ \mu\text{m sec}^{-1}$), which lead to proposals of dynein f as a modulator of motility (Bower *et al.*, 2009; Kotani *et al.*, 2007; Wirschell *et al.*, 2007).

Dynein c proteins is a processive fastest motor (Sakakibara *et al.*, 1999). Dynein c mutant reduces velocity in viscous media. Mutant of single-headed IAD of *Tetrahymena*, DYH8 (IAD-3), DYH9 (IAD-4), and DYH12 (IAD-3) mutants swim $\sim 70\%$ velocity (Liu *et al.*, 2004). Only DYH8 mutant shows frequency reduction. All the three mutants exhibit a more sensitive reversal reaction (Liu *et al.*, 2005).

Regulatory Components

Localized dynein control by downstream signal will be the mechanism of bending motion (Elam *et al.*, 2009; Porter and Sale, 2000). Various biochemical reactions regulate dynein: phosphorylation utilizing such kinases as PKA (Salathe, 2007) and CK1 (Gokhale *et al.*, 2009), AKAP (Gaillard *et al.*, 2001, 2006), and phosphatases (PP1, PP2A) (Habermacher and Sale, 1996, 1997; Yang *et al.*, 2000). ODA α -HC is phosphorylated at the sites near the AAA1 and C-term (King and Witman, 1994). Calcium is another regulatory factor (King, 2010; Salathe, 2007). Calcium (and Cyclic adenosine monophosphate (cAMP)) induces alteration of waveform between symmetric and asymmetric waveform (Hasegawa *et al.*, 1987; Kamiya and Witman, 1984; Omoto and Brokaw, 1985). To elucidate the mechanism of waveform formation it is essential to identify and characterize the regulatory components and their signal transduction pathway, which will regulate axonemal dynein HCs in the end.

Intermediate Chains and Light Chains

OAD has WD-repeat ICs and LCs as well as other coiled-coil proteins (reviews in King, 2010, 2012). IC1 and IC2 are essential for ODA assembly (Fowkes and Mitchell, 1998). In *Chlamydomonas* mutation and knockdown of LC1, which has a leucine-rich repeat and binds to γ -dynein and tubulin (Benashski *et al.*, 1999; Wu *et al.*, 2000), results in reduced velocity and stalled beat (Rompolas *et al.*, 2010). ODA

contains a few redox-sensitive components (Wakabayashi, 2009), while LC4 (42% identical to calmodulin) and IC1 are Ca^{2+} sensitive (Sakato and King, 2003).

ODA is preassembled in the cytoplasm and transported by IFT with adaptors such as Oda16p, a WD-repeat protein (Ahmed *et al.*, 2008) and LC8 (Pazour *et al.*, 1998). Lis1 (see 'Lis1 and NudE') is found also in mammalian respiratory and oviduct cilia and known to be essential for ODA assembly (Pedersen *et al.*, 2007; Rompolas *et al.*, 2012). ODA7, a protein with a leucine-rich repeat and a coiled-coil, is also necessary for assembling α -HC and interacts with ODA and dynein f (Freshour *et al.*, 2007). To anchor ODA on MTD, docking complex, including coiled-coil proteins (DC1 and DC2) are necessary (Koutoulis *et al.*, 1997; Owa *et al.*, 2014; Takada *et al.*, 2002).

Dimeric IAD f has a large complex of ICs and LCs (Figure 7(a); Table 1). The following ICs and LCs were identified: IC138, IC97, FAP120, and LC7b form a phosphoregulatory subcomplex (Bower *et al.*, 2009; Ikeda *et al.*, 2009; Wirschell *et al.*, 2009). IC138 is phosphoprotein and its phosphorylation inactivates dynein f (Porter and Sale, 2000; Wirschell *et al.*, 2007; Yang and Sale, 2000). Hyperphosphorylation of IC138 is involved in control of flagella beating (Habermacher and Sale, 1997). IC97 is non-WD IC (Wirschell *et al.*, 2009). FAP120 is an ankyrin-repeat protein. IC140, LC8, Tctex1, Tctex2b, and LC7a form another subcomplex (Perrone *et al.*, 1998; Yang and Sale, 1998; Figure 7).

Monomeric IADs have centrin, actin (Piperno and Luck, 1979; Yanagisawa and Kamiya, 2001), and p28 (a LC) (LeDizet and Piperno, 1995) (summarized in Table 1). Until now no ICs have been found in single-headed IADs. Dynein d binds p38 (Yamamoto *et al.*, 2006) and p44 (Yamamoto *et al.*, 2008). These two proteins are homologs of LIC (30–60 kDa LC in cytoplasmic dynein) (King *et al.*, 1996; Yamamoto *et al.*, 2006, 2008).

RS and Central Pair

The RS is a complex of 23 proteins (it is not known how many copies of each component exist in one complex) (Yang *et al.*, 2006), protruding from MTD toward the CP (Goodenough and Heuser, 1985). Since RS includes calmodulin (Yang *et al.*, 2001, 2006), RS is supposed to be responsible for calcium-induced alteration of waveforms. There are either two (such as *Chlamydomonas*) or three (such as *Tetrahymena*) RSs within a 96 nm periodic unit. The N-terminal tail part of the singlet IAD is merged with RS (Pigino *et al.*, 2011; Figure 7(b)), suggesting interaction between them. Since RS is required for normal motility and contains AKAP, calmodulin, and PKA, it is likely the transducer and a dynein regulator (Porter and Sale, 2000; Smith and Yang, 2004; Wirschell *et al.*, 2007), although the detailed molecular mechanism of signal transduction is not known.

There are a few studies indicating multiple pathways to regulate dyneins to generate bending motion (reviewed in Kamiya and Yagi, 2014). Paralyzed RS/CP mutants are rescued by nucleotide concentration or mechanical stimulation, but only in the presence of ODA (Frey *et al.*, 1997; Hayashibe *et al.*, 1997; Kamiya, 2002; Yagi and Kamiya, 2000). Sliding velocity

Figure 7 Connection between dyneins and other ciliary components. (a) Possible positions of IC/LC are plotted on the cryo-ET structure. Based on data from Bower, R., VanderWaal, K., O'Toole, E., *et al.*, 2009. IC138 defines a subdomain at the base of the I1 dynein that regulates microtubule sliding and flagellar motility. *Molecular Biology of the Cell* 20, 3055–3063; Oda, T., Kikkawa, M., 2013. Novel structural labeling method using cryo-electron tomography and biotin-streptavidin system. *Journal of Structural Biology* 183, 305–311; Perrone, C.A., Yang, P., O'Toole, E., Sale, W.S., Porter, M.E., 1998. The *Chlamydomonas* IDA7 locus encodes a 140-kDa dynein intermediate chain required to assemble the I1 inner arm complex. *Molecular Biology of the Cell* 9, 3351–3365; and Yamamoto, R., Song, K., Yanagisawa, H.-A., *et al.*, 2013. The MIA complex is a conserved and novel dynein regulator essential for normal ciliary motility. *Journal of Cell Biology* 201, 263–278. (b) RS (blue) and IAD (cyan) are connected at the base, suggesting the pathway of signal transduction for dynein regulation. Based on the data from Pigino, G., Bui, K.H., Maheshwari, A., *et al.*, 2011. Cryo-electron tomography of radial spokes in cilia and flagella. *Journal of Cell Biology* 195, 673–687.

is increased in RS/ODA double mutants (Smith and Sale, 1992). These studies indicate pathways to regulate dyneins by RS-IDA and ODA are independent or compensatory. IC138, phosphorylation of which inhibits dynein f, plays an important role of the RS-IDA pathway. When CP/RS is defective, IC138 phosphorylation is abnormal, resulting in reduced velocities (Habermacher and Sale, 1997; Hendrickson *et al.*, 2004). Kinase inhibitors rescue sliding (Gokhale *et al.*, 2009; Yang and Sale, 2000). This suggests dynein f and IC138 phosphorylation are targets for RS. Based on morphological changes of RS, steric collision was hypothesized as the cause of RS/CP interaction (Mitchell and Nakatsugawa, 2004; Warner and Satir, 1974). Genetic tagging to increase the volume of RS rescues paralyzed deletion mutant of CP proteins, supporting this hypothesis (Oda *et al.*, 2014).

Axonemal Dynein-Related Ciliopathies

Dynein-related ciliopathy such as primary ciliary dyskinesia (PCD) was identified from respiratory cilia lacking dynein

arms from patients with Kartagener's syndrome (Afzelius *et al.*, 1975; Pedersen and Rebbe, 1975).

Cilia in PCD defecting DNAH11 shows deficient in IC78/IC1, similar to *Chlamydomonas* oda9 mutant (Pennarun *et al.*, 1999), indicating assembly defect of ODA in the distal part (Fliegauf *et al.*, 2007). DNAH5 mutation causes random left/right asymmetry (Fliegauf *et al.*, 2005; Olbrich *et al.*, 2002) and hydrocephalus, situs inversus, respiratory infection in mouse (Ibañez-Tallon *et al.*, 2002; Olbrich *et al.*, 2002). Patients with mutation of DNAH11, an ortholog of *Chlamydomonas* β -HC and abundant in the node, suffer from cystic fibrosis (Bartoloni *et al.*, 2002). DNAH11 mutant shows defect in LR determination in mice (Supp *et al.*, 1997) and reduced flow in the Kupffer's vesicle and in the spinal cord and causes hydrocephals in zebrafish (Essner *et al.*, 2005; Kramer-Zucker *et al.*, 2005). Mutation of DNAH2, an ortholog of *Chlamydomonas* IC69 (IC2), defects assembly of ODA (Loges *et al.*, 2008, 2009).

Defect of essential genes for dynein assembly can be a cause of PCD. Cytoplasmic assembly factor, kintoun (ktu), is a member of PIH group and related to PCD (Omran *et al.*,

2008). Depletion of PF13, *Chlamydomonas* ortholog of ktu, causes failure of ODA and IDA assembly (Huang *et al.*, 1979; Omran *et al.*, 2008). Another PIH protein, MOT48, encoded at IDA10, is required for assembly of dyneins b, c, d, and e (Yamamoto *et al.*, 2010), suggesting that this type of PCD is caused by ODA defect. Lacking LRRC50 defects ODA and IDA (Fowkes and Mitchell, 1998; Freshour *et al.*, 2007; Sullivan-Brown *et al.*, 2008; Supp *et al.*, 1997), disrupting DNAH9 (distal), DNAH5, and DNAI2, causing PCD.

PCD (airway, left/right, and immotile sperm) is caused also from DNALI1 (IAD) (Zariwala *et al.*, 2013). Morphological change in DRC and IAD were found. Mouse DNAH1 knockout (dynein d homolog) (Neesen *et al.*, 2001) reduces beat frequency of tracheal cilia and incapability of sperm swimming in viscous media (Woolley *et al.*, 2005).

Architecture and Dynamics of the Mitotic Spindle

The mitotic spindle is a bipolar, spindle-shaped molecular ‘machine’ that is assembled at the onset of mitosis. Its main function is to accurately distribute the chromosomes into two daughter cells during cell division (for detailed recent reviews see [Helmke et al., 2013](#); [McIntosh et al., 2012](#)). Any failure in this critical role could lead to development of diseases, including cancer ([Noatynska et al., 2012](#); [Orticello et al., 2014](#)), emphasizing the robustness of the mitotic spindle apparatus as an absolute requirement for normal tissue development.

The first insight into the shape and structure of the mitotic spindle and its connection with chromosomes was provided in the early 1880s by the detailed drawings of Walther Flemming (reproduced in [Flemming, 1965](#)), making this research field over a century old. More than 50 years later, in the late 1930s, followed up in the 1950s, it became possible to confirm the existence of this fibrous structure in living cells owing to the invention and implementation of polarized light microscopy ([Schmidt, 1937](#); [Inoue, 1953](#)). In a series of experiments it was shown that spindle fibers, which we now know to be formed by microtubules, could disappear by lowering the temperature or by adding the disassembling agent colchicine (reviewed in [Inoue, 1981](#)). This process was reversible if the temperature was increased or if the colchicine was washed out, postulating the dynamic and polymeric nature of microtubules. By isolating and identifying the target of colchicine, it was confirmed that microtubules are indeed polymers, with a protein called tubulin being their main building unit ([Borisy and Taylor, 1967](#); [Mohri, 1968](#)).

Research over the following decades revealed that each microtubule is a hollow cylindrical structure normally composed of 13 laterally associated protofilaments that are assembled out of heterodimers of α - and β -tubulin molecules. The head-to-tail arrangement of α and β subunits causes the intrinsic polarity to microtubules, with α -tubulin exposed at the so-called minus end and β -tubulin at the plus end. Although tubulins are GTP-binding proteins, only the β subunit acts as a GTPase once a new heterodimer has been added. After GTP has been hydrolyzed into GDP, the heterodimers have a tendency to bend, which destabilizes the linear array and results in plus-end depolymerization. This, however, happens with a delay that is long enough to allow the accumulation of GTP-bound β -tubulin at the plus end and formation of a GTP-cap, which keeps the heterodimers straight and, consequently, stabilizes the protofilaments. Lateral interactions between the protofilaments prevent previously integrated heterodimers from bending even when their GTP has been hydrolyzed, resulting in energy storage along the microtubule lattice (reviewed in [Howard and Hyman, 2009](#)). Sudden loss of the GTP-cap causes curving of the tubulin heterodimers and rapid depolymerization of microtubule plus ends ([Chretien et al., 1995](#); [Mandelkow et al., 1991](#)), accompanied by the release of stored energy that can be harvested to facilitate cell division, e.g. by promoting the movement of chromosomes bound to depolymerizing microtubules. This transition from growth to shrinkage is termed ‘catastrophe,’ while regrowth of shrinking microtubules upon the retrieval of their GTP-cap is called ‘rescue.’ The ability of microtubules to rapidly switch between these two states is known as ‘dynamic instability’ ([Mitchison](#)

and Kirschner, 1984). However, the dynamic instability of microtubules is not uniform across the different stages of the cell cycle, becoming more dynamic during mitosis.

Different Paths of Spindle Assembly

In higher eukaryotes, mitotic spindle assembly starts with nuclear envelope breakdown in the prophase and relies largely on dynamic instability. Almost all animal cells contain centrosomes as the main microtubule organizing centers; these are duplicated in the interphase and separated at the onset of mitosis. Centrosomes consist of a pair of centrioles embedded in a pericentriolar material in which multiple copies of the γ -tubulin ring complex (γ -TuRC) are clustered and linked by coiled-coil proteins, such as pericentrin and ninein (Mennella *et al.*, 2014). γ -TuRC makes microtubule minus ends less dynamic by anchoring them at the centrosome, while providing the template for microtubule growth and defining their polarity (reviewed in Kollman *et al.*, 2011).

As soon as the nuclear envelope breaks, the barrier between the cytoplasm and the nucleus vanishes and microtubules can freely interact with chromosomes. At this stage, centrosomes mature and are able to nucleate 5–10 times more microtubules than in the interphase (Snyder and McIntosh, 1975). These dynamic microtubules nucleated from the centrosomes are known as astral microtubules. As a result of centrosome maturation and more frequent switches between growth and shrinkage due to dynamic instability, astral microtubules greatly increase their chances of interacting with chromosomes. This interaction is stabilized at the kinetochore, a structural component at the centromeric region built from more than a hundred different proteins (Cheeseman and Desai, 2008). Such random exploration of the cell space by dynamic astral microtubules in their search for chromosomes is known as ‘search-and-capture’ (Kirschner and Mitchison, 1986). However, computational studies have shown that spindle assembly could not rely exclusively on dynamic instability, since search-and-capture of all kinetochores would require several hours, in contrast to the observed spindle assembly time in living mitotic cells (Wollman *et al.*, 2005; Paul *et al.*, 2009). High-resolution time-lapse imaging, followed by 3D reconstructions, revealed that chromosome positioning during the prometaphase significantly facilitates search-and-capture and chromosome congression (Magidson *et al.*, 2011). This study showed that polar ejection forces (PEFs) generated by the plus-end directed motor proteins chromokinesins promote a toroid, ring-like arrangement of chromosomes that are laterally attached to the surface of the forming spindle. This promotes kinetochore exposure to a microtubule-dense area while preventing kinetochores from being shielded by other chromosomes.

The absence of centrosomes in most meiotic and plant spindles suggests, however, the existence of an alternative pathway of spindle assembly. The ‘self-organization’ of spindle assembly was clearly revealed using *Xenopus* egg extracts. In this system, spindles could be successfully formed, even in the absence of centrosomes, just by adding either whole chromosomes or even only chromatin-coated beads to the cell extracts (Heald *et al.*, 1996). Microtubule polymerization

around chromosomes is driven by the stabilizing effect of GTP-bound Ran molecules (Carazo-Salas *et al.*, 1999, 2001), which are brought to chromatin through their interaction with the guanine nucleotide exchange factor RCC1, establishing a concentration gradient throughout the cytoplasm (Kalab *et al.*, 2002). This Ran-GTP gradient is thought to release spindle assembly factors such as TPX2 from the inhibitory effect of Importin, favoring microtubule nucleation (Gruss and Vernos, 2004). However, in spite of a well-documented role of the Ran-GTP gradient in acentrosomal spindle assembly in *Xenopus* eggs, in other systems it does not seem to play an essential role (Dumont *et al.*, 2007; O’Connell *et al.*, 2009; Moutinho-Pereira *et al.*, 2013).

Although the ability of spindle assembly around chromatin-coated beads excluded an essential role for kinetochores in this process (Heald *et al.*, 1996), chromosome-based microtubule polymerization is strongest at the kinetochores (Pease, 1946; Snyder and McIntosh, 1975; Witt *et al.*, 1980; Maiato *et al.*, 2004a; Khodjakov *et al.*, 2003; O’Connell *et al.*, 2009). Careful analysis by serial section electron microscopy revealed that microtubule polymerization is initiated in close proximity to kinetochores (Witt *et al.*, 1980). Kinetochores then capture and stably attach those short-growing microtubule plus ends, for which kinetochores have higher affinity (Huitorel and Kirschner, 1988). This allows for the correct direction of their further growth (with the microtubule plus end situated at the kinetochore and the minus end oriented toward the pole) (Maiato *et al.*, 2004a).

Importantly, chromatin-based microtubule polymerization is complementary to search-and-capture in cells containing centrosomes. Remarkably, spindle formation was still occurring in cells with mutations that destroyed the functionality of centrosomes (Bonaccorsi *et al.*, 1998; Basto *et al.*, 2006; Megraw *et al.*, 2001; Debec *et al.*, 1982; Sir *et al.*, 2013), as well as in the cells in which centrosomes were physically removed or destroyed (Khodjakov *et al.*, 2000; Hinchcliffe *et al.*, 2001). However, the function of these spindles was somewhat compromised, showing that, even though they are not essential for spindle assembly, centrosomes are still important for the accuracy of cell division in some systems that normally have them (Khodjakov and Rieder, 2001; Sir *et al.*, 2013).

Computer-based simulations showed that a two-motor system would be sufficient to assemble the spindle in a chromatin-based manner. In this system, which the authors named ‘slide-and-cluster,’ a plus end-directed motor slides microtubules from the chromatin toward the pole, where they are clustered and focused by a minus end-directed motor (Burbank *et al.*, 2007). This model is in line with observations that some spindles are assembled as ‘tiled arrays’ from a larger number of short microtubules that are cross-linked by motor proteins and MAPs (Yang *et al.*, 2007a). Using laser microsurgery to ablate microtubules inside the large spindles of *Xenopus* egg extracts, it was recently shown that these spindles consist of microtubules of inhomogeneous lengths, with their plus and minus ends distributed throughout the spindle, indicating the importance of spatial variation in microtubule nucleation combined with the local transport of short microtubules (Brugues *et al.*, 2012).

An additional mechanism, which might significantly contribute to the efficiency of mitotic spindle assembly, depends

on non-centrosome- and non-chromatin-mediated microtubule nucleation initiated by Augmin. Augmin is an eight-subunit protein complex that recruits γ -TuRC to the outer lattice of preexisting microtubules, initiating their branching through the polymerization of new microtubules from within the spindle (Goshima *et al.*, 2008; Uehara *et al.*, 2009; Kamasaki *et al.*, 2013). Interestingly, RNAi-mediated knock-down of Augmin showed more severe spindle phenotypes in systems without functional centrosomes (Petry *et al.*, 2011; Goshima *et al.*, 2008; Uehara *et al.*, 2009), highlighting the importance of the interplay between different assembly pathways in the formation of an efficient spindle machinery.

The Role of Motors and MAPs in Mitotic Spindle Assembly

Microtubules in living cells exhibit more dynamic behavior compared to microtubules reconstituted *in vitro*, which suggests the existence of additional stabilizing and destabilizing factors in living cells (Desai and Mitchison, 1997). A large number of microtubule-associated proteins (MAPs) and motor proteins that affect the stability of microtubules were revealed through biochemical and proteomic approaches, as well as genetic and genome-wide RNAi-based screens (Bonner *et al.*, 2011; Gache *et al.*, 2010; Goshima *et al.*, 2007; Moutinho-Pereira *et al.*, 2013; Maiato *et al.*, 2004b). While MAPs directly influence microtubule stability through their interaction with the microtubule lattice and/or ends, motor proteins use ATP hydrolysis to provide the energy used either to destabilize the microtubule lattice or to transport different cargos along the microtubules, both of which have an impact on the efficiency of mitotic spindle assembly.

Microtubule Cross-Linkers

Another important property of several different MAPs and motors that contributes to spindle assembly and maintenance is their ability to cross-link microtubules. One of the most studied microtubule cross-linkers is Eg5, a member of the kinesin-5 protein family. Eg5 is a plus end-directed motor that assembles into homo-tetramers with two-motor domains located on each of the opposite sides of the complex (Cole *et al.*, 1994). This allows it to bind two different microtubules and, because of its preference for antiparallel microtubules (Van Den Wildenberg *et al.*, 2008), to slide their minus ends away from each other (Sharp *et al.*, 1999). Inhibition of Eg5 prevents assembly of a bipolar spindle, leading to formation of monopolar asters (Kapoor *et al.*, 2000; Blangy *et al.*, 1995). However, once spindle bipolarity has been achieved, Eg5 is not required to maintain it, due to the cooperative activity of another homo-tetramer microtubule cross-linker, Kif15, which was proposed to share the ability to slide antiparallel microtubules with Eg5 (Tanenbaum *et al.*, 2009; Vanneste *et al.*, 2009; Drechsler *et al.*, 2014).

An additional cross-linker of antiparallel microtubules is PRC1, which is involved in the assembly of the central spindle during late mitosis. During early mitosis, CDK1 and Plk1 phosphorylate PRC1, keeping it mostly inactive (Zhu *et al.*, 2006; Hu *et al.*, 2012). At anaphase onset it is activated

by dephosphorylation and then brought to the plus ends of antiparallel microtubules of the midzone by the plus end-directed motor protein Kif4A (Zhu and Jiang, 2005). It was recently shown that Aurora B kinase regulates relocation of Kif4A from the chromosome arms to the spindle midzone, as well as its interaction with PRC1 and the ability to suppress microtubule dynamics, which plays an important role in the regulation of spindle elongation and cytokinesis (Nunes Bastos *et al.*, 2013).

In addition to the described microtubule plus end-directed motors, two minus end-directed motor proteins also have the ability to cross-link microtubules and contribute to efficient mitotic spindle assembly. Dynein, a 1.6-MDa multisubunit protein complex (Allan, 2011), and its binding partner dynactin recruit NuMA to the spindle poles to cross-link and focus microtubules (Merdes *et al.*, 1996). Moreover, a recent *in vitro* study showed that Dynein alone is also able to cross-link and slide antiparallel microtubules (Tanenbaum *et al.*, 2013), resulting in the generation of an inward force within the spindle and further explaining the antagonizing effect on outward microtubule sliding forces generated by Eg5 (Ferenz *et al.*, 2009) and possibly Kif15. The other minus end-directed motor protein involved in spindle assembly is HSET (Kinesin 14). This kinesin has the ability to cross-link and slide antiparallel microtubules, generating an inward force within the spindle, similar to that proposed for Dynein (Fink *et al.*, 2009; Mountain *et al.*, 1999), and is required for kinesin-5-driven microtubule sliding (Hepperla *et al.*, 2014). Thus, without the assistance of kinesin-14, kinesin-5 fails to cross-link microtubules and cannot generate the outward force required for spindle elongation, resulting in short spindles.

Microtubule Polymerization-Promoting Proteins

Many MAPs contribute to spindle assembly and maintenance through their stabilizing effect on microtubules. A significant fraction of MAPs belong to the microtubule plus end tracking protein family or +TIPs, including members of the CLIP, CLASP, and TOG protein families (Ferreira *et al.*, 2014). CLIP170 stabilizes microtubules by promoting rescue events (Arnal *et al.*, 2004; Komarova *et al.*, 2002) and helps to maintain spindle bipolarity by counteracting outward microtubule sliding through interaction with Dynein (Tanenbaum *et al.*, 2008). Proteins of the CLASP family (CLASP1 and CLASP2 in mammals) also promote microtubule rescue events (Akhmanova *et al.*, 2001; Al-Bassam *et al.*, 2010). Depletion of CLASPs resulted in shorter, collapsed, and multipolar spindles (Maiato *et al.*, 2003, 2002; Logarinho *et al.*, 2012; Mimori-Kiyosue *et al.*, 2006; Lemos *et al.*, 2000; Pereira *et al.*, 2006), highlighting their role in bipolar spindle organization. The *Xenopus* member of the TOG protein family, XMAP215, promotes microtubule polymerization at the plus ends (Gard and Kirschner, 1987; Brouhard *et al.*, 2008), and its depletion prevents bipolar spindle assembly, resulting in short spindles (Tournéize *et al.*, 2000). RNAi-mediated knockdown of its mammalian homolog, ch-TOG, also affected mitotic spindle assembly, resulting in disorganized and multipolar spindles (Gergely *et al.*, 2003). In addition to its growth-promoting effect, ch-TOG also contributes to microtubule stabilization by

protecting kinetochore microtubules from depolymerization by MCAK (Barr and Gergely, 2008).

Another protein that specifically stabilizes k-fibers is HURP. HURP is localized to kinetochore microtubules in a Ran-GTP-dependent manner (Sillje *et al.*, 2006) and promotes chromatin-induced spindle assembly (Casanova *et al.*, 2008). HURP depletion impaired the stability of k-fibers, leading to chromosome congression problems (Wong and Fang, 2006; Sillje *et al.*, 2006), while its overexpression increased microtubule stability (Wong and Fang, 2006). Depletion of its *Drosophila* ortholog, Mars, resulted in mitotic spindle malformations due to the lack of kinetochore microtubules (Yang and Fan, 2008).

Besides the plus ends, MAPs are able to stabilize microtubule minus ends as well. Both Patronin (Goodwin and Vale, 2010; Hendershott and Vale, 2014; Jiang *et al.*, 2014) and MCRC1 (Meunier and Vernos, 2011; Petry and Vale, 2011) localize specifically to the microtubule minus ends, where they prevent their kinesin-13-mediated depolymerization.

Microtubule Depolymerization-Promoting Proteins

The best studied member of the kinesin-13 motor protein family is MCAK, which localizes to the spindle poles, centromeres, kinetochores, and microtubule plus ends, where it can use the energy from ATP hydrolysis to depolymerize microtubules from both ends (Ems-McClung and Walczak, 2010). Its ortholog in *Xenopus*, XKCM1, was shown to negatively regulate microtubule growth, as its depletion in egg extracts interfered with spindle assembly, creating abnormally long microtubules (Walczak *et al.*, 1996). In mammals, microtubule length was less affected in MCAK-depleted cells, but strongly increased by knocking down Kif2A, another member of the kinesin-13 protein family (reviewed in Ems-McClung and Walczak, 2010), emphasizing a conserved role of kinesin-13 in mitotic spindle assembly. *In vitro* reconstitution experiments with MCAK and Kif2A *Xenopus* orthologs demonstrated their direct microtubule-destabilizing activity, showing that these proteins were able to completely depolymerize chemically stabilized microtubules (Desai *et al.*, 1999).

Microtubule growth is also regulated by members of the kinesin-8 motor protein family (Kif18A in mammals), as their depletion from cells also results in elongated microtubules. Kinesin-8 proteins are highly processive motors, which accumulate at microtubule plus ends and, once the plus ends become saturated, they initiate microtubule disassembly in a length-dependent manner (reviewed in Wordeman, 2010).

Finally, the microtubule-severing proteins Katanin, Spastin, and Fidgetin disassemble microtubules in a completely different manner, using ATP hydrolysis to cut microtubules into shorter fragments. They bind to the tubulin C-terminal tails at the surface of the microtubule lattice and initiate microtubule depolymerization by removing tubulin subunits from it (Sharp and Ross, 2012). Loss of katanin in *Caenorhabditis elegans* resulted in disorganized spindles with fewer microtubules, but this phenotype is weaker in mammals, probably due to the presence of centrosomes that might compensate by increasing microtubule nucleation (reviewed in Sharp and Ross, 2012). In *Drosophila* S2 cells, microtubule-severing proteins also play a role in poleward chromosomal movements

during anaphase A by inducing depolymerization of kinetochore microtubules' plus and minus ends (Zhang *et al.*, 2007).

Mitotic Spindle Properties

The mitotic spindle is a highly dynamic molecular machine, in which forces generated by microtubule dynamics and motor proteins must balance out at steady state. Next we discuss some of the spindle properties that result from this balance.

Microtubule Turnover

Development of microscopy techniques such as photo-bleaching, photo-activation, and photo-conversion have revealed that spindle microtubules turn over rapidly, exhibiting typical half-lives of several seconds to several minutes. For instance, astral microtubules are less stable than kinetochore microtubules. Microtubule turnover does not differ only between different types of microtubules, but also varies within the same microtubule population depending on the mitotic stage. Accordingly, kinetochore microtubules become more stable toward the later stages of mitosis, with their turnover decreasing from prometaphase to metaphase and finally to anaphase (Zhai *et al.*, 1995; Gorbisky and Borisy, 1989; Kabeche and Compton, 2013). Kinetochore microtubule turnover depends on the tension established between sister kinetochores (Nicklas and Koch, 1969), and on CDK1 kinase activity regulated by Cyclins A and B (Kabeche and Compton, 2013).

Poleward Microtubule Flux

In metaphase, spindle size and shape is at steady state, but microtubules remain highly dynamic. This translates into another dynamic property, the so-called microtubule poleward flux, discovered by photo-activation of microtubules labeled with caged fluorescent tubulin (Mitchison, 1989). Although undetectable in yeast, this feature is highly conserved in higher eukaryotes. It is defined by the translocation of tubulin dimers added at the microtubule plus ends and their simultaneous removal at the minus ends (Mitchison *et al.*, 1986), generating a continuous poleward motion of tubulin subunits inside spindle microtubules. Further advances in the investigation of this cellular phenomenon were achieved using fluorescence speckle microscopy (FSM) (reviewed in Barisic *et al.*, 2012). FSM-based studies revealed that different classes of microtubules display different flux rates, from which the astral microtubules did not flux at all (Waterman-Storer *et al.*, 1998; Maddox *et al.*, 2003; LaFountain *et al.*, 2004).

Although it is widely accepted that the flux of the interpolar microtubules is driven by kinesin Eg5, which interconnects and slides antiparallel microtubules, the origin of kinetochore microtubule flux is still debatable. One view is that it is driven by kinesin-13-mediated depolymerization at the microtubule minus ends (reviewed in Kwok and Kapoor, 2007; Shimamoto *et al.*, 2011). Another view is that flux relies on the coupling of microtubules within the spindle (Shimamoto *et al.*, 2011; Itabashi *et al.*, 2009), likely through the action of microtubule

cross-linking proteins (see above). In this model, microtubule cross-linkers transduce the force generated by motor-driven sliding of interpolar microtubules (Brust-Mascher and Scholey, 2002; Matos *et al.*, 2009; Pereira and Maiato, 2012). Interestingly, RNAi-mediated depletion of chromokinesin Kif4A also decreases kinetochore microtubule flux, but it remains unknown whether this is a direct role or results from unbalanced spindle forces (Wandke *et al.*, 2012). Kif4A is localized exclusively at the chromosome arms during metaphase, where it interacts with non-kinetochore microtubules and actively participates in the generation of polar ejection forces (PEFs) (Barisic *et al.*, 2014). As chromosomes align to the metaphase plate, Kif4A cannot push chromosomes further away from the pole due to equivalent forces applied from the opposite pole. However, Kif4A remains processive on the interacting microtubules and might result in the generation of kinetochore microtubule flux by the action of cross-linking molecules. This view is also supported by the recent observation that the movements of neighboring sister kinetochore pairs in metaphase are correlated and could be explained by simulating elastic cross-linkers between kinetochore microtubules (Vladimirov *et al.*, 2013).

Although inhibition of poleward microtubule flux did not affect spindle assembly and chromosome alignment, it increased chromosome missegregation, highlighting its importance for accurate cell division (Ganem *et al.*, 2005). This negative consequence of microtubule flux abrogation could be explained through the role of flux-driven microtubule slippage at kinetochores, which facilitates error correction and equal distribution of spindle forces along the metaphase plate (Matos *et al.*, 2009).

Spindle Length Control

Significant progress in our understanding of the mechanisms behind spindle length control was obtained from the relationship between spindle size and cell size in meiotic and mitotic divisions during *Xenopus* development, as well as in meiotic and mitotic *Xenopus* cell extracts (reviewed in Goshima and Scholey, 2010). Accordingly, the cell wall and/or cytoplasmic material are limiting factors for spindle growth. However, cells reach a plateau in spindle size, after which the correlation is lost, indicating that in addition to cell size, some intrinsic mechanisms must control spindle length (Goshima and Scholey, 2010). These conclusions were elegantly confirmed in two recent studies in which droplets of different sizes containing mitotic *Xenopus* extracts were generated using microfluidics (Hazel *et al.*, 2013; Good *et al.*, 2013). These studies concluded that the amount of cytoplasmic material is a limiting factor that ultimately defines spindle length.

Some of the mechanisms that directly affect the regulation of spindle size involve polymerization- and depolymerization-promoting factors, cross-linking motor proteins involved in microtubule sliding, microtubule branching and severing proteins, poleward microtubule flux, and microtubule nucleation from chromosomes (reviewed in Goshima and Scholey, 2010). In addition, a strong correlation between centrosome size and spindle length has been reported (Greenan *et al.*, 2010), possibly due to enhanced microtubule nucleation from larger centrosomes, as well as the stronger pulling effect

of cortical dynein on a larger number of astral microtubules (Grill *et al.*, 2003).

Visco-Elastic Nature of the Mitotic Spindle

Deeper insight into the mechanical properties of the spindle was provided using micromechanical tools combined with high-resolution fluorescence imaging of metaphase spindles from *Xenopus* egg extracts. When spindles were compressed parallel to their axis by two cantilevers, one of them working as a force sensor and the other as a manipulator, they were able to completely recover their original shape if the applied force was not above a certain threshold, suggesting the existence of elastic properties. However, the recovery process after compression was slower than expected for strictly elastic elements, suggesting visco-elastic properties (Itabashi *et al.*, 2009). Application of forces above the threshold led to plastic irreversible deformations. Additionally, the observation of visco-elastic behavior suggested the existence of coupling elements between spindle microtubules, strengthening previous micromanipulation studies in grasshopper spermatocytes (Itabashi *et al.*, 2009; Nicklas *et al.*, 1982). Spindle micromanipulation by two force-calibrated microneedles further confirmed the visco-elastic behavior of spindles and showed that it indeed depends on microtubule cross-linking (Shimamoto *et al.*, 2011). Finally, spindle visco-elasticity was also confirmed in a recent study in which a stretching force was applied to spindles (Takagi *et al.*, 2014).

Mitotic Spindle Function
